Abstract

Recent empirical approaches in forecasting equity returns or premiums found that dynamic interactions among the stock and bond are relevant for long term pension products. Automatic procedures to upgrade or downgrade risk exposure could potentially improve long term performance for such products. The risk and return of bonds is more easy to predict than the risk and return of stocks. This and the well known stock-bond correlation motivates the inclusion of the current bond yield in a model for the prediction of excess stock returns. Here, we take the actuarial long term view using yearly data, and focus on nonlinear relationships between a set of covariates. We employ fully nonparametric models and apply for estimation a local-linear kernel smoother. Since the current bond yield is not known, it is predicted in a prior step. The structure imposed this way in the final estimation process helps to circumvent the curse of dimensionality and reduces bias in the estimation of excess stock returns. Our validated stock prediction results show that predicted bond returns improve stock prediction significantly.

1. Introduction and Motivation

For a long time predicting asset returns has been a main objective in the empirical finance literature. It started with predictive regressions of independent variables on stock market returns. Typically, valuation ratios are used that primarily characterise the stock, for example the dividend price ratio, the dividend yield, the earnings price ratio or the book-to-market ratio. Other variables related to the interest rate like treasury-bill rates and the long-term bond yield, or macroeconomic indicators like inflation and the consumption wealth ratio, are often incorporated to improve prediction. For a detailed overview we refer to the examples and discussion in Rapach et al. (2005) or Campbell and Thompson (2008).

In this paper, we take the actuarial long term view using yearly data, and focus on nonlinear relationships between a set of covariates. There are not many historical years in our records and data sparsity is of great importance in our approach. One could also use data of higher frequency as weekly or daily data, but one has to remember that the logistics of prediction is then very different. In our approach using yearly data bias might be of big importance while variance becomes less of an issue. In other words, the usual variance-bias trade-off depends on the horizon. An adequate model for monthly data might perform worse for yearly data and vice versa. The reason for the use of yearly data is our interest in actuarial models of long term savings and their possible econometric improvement (see e.g. Bikker et al. (2012), Guillen et al. (2013a), Guillen et al. (2013b), Owadally et al. (2013), Guillen et al. (2014), or Gerrard et al. (2014)). Our favored methodology of validating the fully nonparametric models that we employ for the long term yearly data also originates from the actuarial literature (see Nielsen and Sperlich (2003)).

The apparent predictability found by many authors was controversially discussed. As Lettau and Nieuwerburgh (2008) note, correct inference is problematic due to the high persistence of financial ratios, which have poor out-of sample forecasting power that moreover shows significant instability over time. Therefore, the question of whether empirical models are really able to forecast the equity premium more
accurately than the simple historical mean was intensively debated in the finance literature. Recently, 
Goyal and Welch (2008) fail to provide benefits of predictive variables compared to the historical mean. In 
contrast, Rapach et al. (2010) recommend a combination of individual forecasts. Their method includes 
the information provided from different variables and reduces this way the forecast volatility. Elliott et al. 
(2013) suggest a new method to combine linear forecasts based on subset regressions and show improved 
performance over the classical linear prediction methods. More recently, Scholz et al. (2015) propose a 
simple bootstrap test about the true functional form to evidence that the null of no predictability of 
returns can be rejected when using information such as earnings.

A direct comparison of stocks and bonds, mostly used by practitioners, makes the so-called FED 
model. It relates yields on stocks, as ratios of dividends or earnings to stock prices, to yields on bonds. 
Asness (2003) shows the empirical descriptive power of the model, but notes also that it fails in predicting 
stock returns. One of his criticisms is the comparison of real numbers to nominal ones. Actually, most 
studies discuss separately the predictability in stock and bond markets. However, Shiller and Beltratti 
(1992) analyse the relation between stock prices and changes in long-term bond yields. Fama and French 
(1993) find that stock returns have shared variation due to the stock-market factors, and they are linked 
to bond returns through shared variation in the bond-market. Engsted and Tanggaard (2001) pose the 
interesting question of whether expected returns on stocks and bonds are driven by the same information, 
and to what extent they move together. In their empirical setting, they find that excess stock and bond 
returns are positively correlated. Aslanidis and Christiansen (2014) adopt quantile regressions to 
scrutinize the realized stock-bond correlation and the link to the macroeconomy. Tsai and Wu (2014) 
analyse the bond and stock market responses to changes in dividends. Lee et al. (2013) find dynamic 
interactions among the stock, bond, and insurance markets. For additional literature on the relation 
between stock and bond returns (especially co-movements, joint distributions, or correlations), see, for 
example, Lim et al. (1998), Ilmanen (2003), Guidolin and Timmermann (2006), Connolly et al. (2010),
Baele et al. (2010), or Bekaert et al. (2010).

One overall idea of the this paper is to exploit the interrelationship of present values of stock returns and bond returns. They are after all both discounted cash flows. Our underlying assumption implies that expected returns are associated with variables related to longer-term aspects of business conditions, as mentioned in Campbell (1987). Consequently, we include in a nonparametric prediction model of excess stock returns the bond yield of the same year. This way, the bond captures a most important part of the stock return, namely the part related to the change in long-term interest rate. Nonlinear forecasting methods are a growing area of empirical research, see for example Guidolin and Timmermann (2006), McMillan (2007), or Guidolin et al. (2009). Nielsen and Sperlich (2003) find a significant improvement in the prediction power of excess stock returns due to the use of nonlinear smoothing techniques. Based on their findings, we focus on nonlinear relationships between a set of covariates and the bond yield of the same year. We apply for estimation a local-linear kernel smoother which nests the linear model without bias. For the purpose of bandwidth selection and to measure the quality of prediction we use a cross-validation measure of performance. It is a generalized version of the validated $R^2$ of Nielsen and Sperlich (2003) and allows for a direct comparison of the proposed model with the historical mean.

An obvious problem is that the current bond yield is unknown. Thus, we have to predict it in a first step. Here, we also employ fully nonparametric models and use a local-linear kernel smoother. This raises the question why it is necessary to use a two-step procedure. One could directly include the variables used for the bond prediction when forecasting stock returns. The problem is that such a model would suffer from the curse of dimensionality and complexity in several aspects: The dimension of the covariates, possible over-fitting, and the interpretability. In nonparametrics it is well known that the import of structure is an appropriate way to circumvent these problems\footnote{An other possibility could be the optimal choice of regressors, see Vieu (1994).}. Furthermore, Park et al. (1997)
showed that an appropriate transformation of the predictors can significantly improve nonparametric prediction. In our approach, we utilize the additional knowledge about the structure that is inherent in the economic process that generates the data. We find that the inclusion of the generated variable shows notable improvement in the prediction of excess stock returns. Note that one does not achieve computational efficiency, but rather estimation efficiency from adding information. To our knowledge we are the first including nonparametrically generated regressors for nonparametric prediction of time series data. Therefore we also have to develop the theoretical justification for the use of constructed variables in nonparametric regression when the data are dependent.

For the empirical part we use annual Danish stock and bond market data (also used in Lund and Engsted (1996), Engsted and Tanggaard (2001), or Nielsen and Sperlich (2003)). We find that the inclusion of predicted bond yields greatly improves the prediction quality of stock returns in terms of the validated $R^2$. With our best prediction model for one-year stock returns we not only beat the simple historical mean but we also observe a large increase in validated $R^2$ from 5.9% to 28.3%. To underline our findings, we also include in our empirical analysis the prediction of the ratio of stock returns and dividend yields getting similar results.

The paper proceeds as follows. Section 2 describes the prediction framework and the measure of validation. The mathematical justification is introduced in Section 3. Section 4 presents our findings from an empirical and a small simulation study. Section 5 concludes. Finally, the Appendix contains proofs of our theoretical results.

2. The prediction framework

In the financial and actuarial literature traditional approaches like the classic $R^2$, the adjusted $R^2$, goodness-of-fit or testing methods are mainly used to measure in-sample forecasting power. More recently, out-of-sample statistics and tests are discussed, see for example Inoue and Kilian (2004), Clark and West
(2006), Goyal and Welch (2008), or Campbell and Thompson (2008). In our study, we use a generalized version of the validated $R^2$ ($R^2_V$) of Nielsen and Sperlich (2003) based on leave-k-out cross-validation. It measures how well a model predicts in the future compared to the historical mean. The classical $R^2$ is often used, easy to calculate and has a straight forward interpretation. But it can hardly be used for prediction nor for comparison issues as it always prefers the most complex model. See also Valkanov (2003) or Dell’Aquila and Ronchetti (2006) for more relevant arguments for disregarding the classical $R^2$ measure when selecting a model. For comparison often the adjusted $R^2$ is applied, which penalises complexity via a degree of freedom adjustment. It is well known that this correction does not work in our case, see for example Sperlich et al. (1999).

The idea of the $R^2_V$ is to replace total variation and not explained variation by their leave-k-out cross-validated analogs. Note that cross-validation (cv) is a quite common in the nonparametric time series context, see Györfi et al. (1990). More formally, consider the two models

$$Y_t = \mu + \varepsilon_t \quad \text{and} \quad Y_t = g(X_t) + \zeta_t,$$

where $\mu$ is estimated by the sample mean $\bar{Y}$ and the unknown function $g$ by local linear kernel regression. The explanatory variables $X_t$ in the fully nonparametric model can be multidimensional vectors containing information from the past – accounting this way for a possible long term dependence. We suppress a subscription for the chosen smoothing parameter $h$, since we always apply the bandwidth $h$ that maximises the $R^2_V$. It is defined as

$$R^2_V = 1 - \frac{\sum_t \{(Y_t - \hat{g}_{-t})^2\}}{\sum_t \{(Y_t - \bar{Y}_{-t})^2\}}, \quad (1)$$

where leave-k-out cross-validated values $\hat{g}_{-t}$ and $\bar{Y}_{-t}$ are used, i.e. the function $g$ and the mean $\bar{Y}$ both are computed removing $k$ observations around the $t$-th point in time. Here we use $k = 1$, the classical leave-one-out cross-validation estimator. We have also checked the robustness of the results for different values of $k$. We found no significant differences between the validated $R^2_V$ values for $k \leq 7$. Note that
cross-validation with \( k = 1 \) is not always appropriate in a time series context, as it is a cross-validation estimator of prediction errors. It is well known that cross-validation for time series often requires to leave out more than one data point and possibly requires some extra correction when the leave-out fraction of data is non-negligible (see, for example, Burman et al. (1994)). Burman and Nolan (1992) give simulation evidence and show that under proper dependence conditions even leave-one-out cross-validation is appropriate. Burman and Nolan (1992) further point out that for stationary processes the test and training set need not to be independent for cross-validation to work. Bandi et al. (2016) show in recent work that the cross-validated bandwidth continues to be optimal with respect to the average squared error even when the data generating process is a \( \beta \)-recurrent Markov chain (covering stationary as well as nonstationary processes).

A possible generalisation of our approach would be the use of the Do-validation principle to obtain more robust validated \( R^2 \)-values. See Mammen et al. (2011) and Gámiz-Pérez et al. (2013) for some recent improvement of the cross-validation approach. Since maximizing the \( R^2_V \) is equivalent to minimize the cross-validation criterion, we also use the \( R^2_V \) to find the optimal prediction bandwidth for the kernel function used (Quartic kernel). Please keep in mind that the choice of the kernel function is automatically corrected by the (adaptive) bandwidth choice, even in small data sets. As the \( R^2_V \) measures how well a given model and estimation principle predicts compared to the historical mean, an \( R^2_V < 0 \) indicates that one predicts worse than the historical mean. Note further that cross validation (and thus the \( R^2_V \)) punishes not just underfitting but also overfitting (pretending a functional relationship that is not real, see Györfi et al. (1990)). This would result in \( R^2_V < 0 \).

In the following, we study excess stock returns defined as

\[
S_t = \log\left\{ \frac{(P_t + D_t)}{P_{t-1}} \right\} - r_{t-1},
\]

where \( D_t \) denotes the (nominal) dividends paid during year \( t \), \( P_t \) the (nominal) stock price at the end of
year \( t \), and \( r_t \) the short-term interest rate, which is \( r_t = \log(1 + R_t/100) \) using the discount rate \( R_t \). In our article, we concentrate on forecasts over the one-year horizon, but also longer periods can easily be included with \( Y_t = \sum_{i=0}^{T-1} S_{t+i} \), the excess stock return at time \( t \) over the next \( T \) years. However, this would pose greater statistical challenges. Based on the motivations from the introduction, we include the same years bond yield as a single regressor or together with further lagged covariates in the model equation, i.e. we consider the model

\[
Y_t = g(\hat{b}_t, v_{t-1}) + \varepsilon_t,
\]

(2)

with the unknown function \( g \), the constructed bond yield \( \hat{b}_t \), a vector of further regressors \( v_{t-1} \) and error terms \( \varepsilon_t \), i.e. mean zero variables given the past. Note again that \( \hat{b}_t \) could be a more general multidimensional regressor which contains elements from the past and accounts for long term dependence. However, in our practical implementation we consider \( \hat{b}_t \) to be the constructed bond yield. In addition, we do not assume any explicit distribution on the asset returns. An explicit understanding of this distribution, see for example Eling (2014), could perhaps enhance efficiency of our estimation. Remember, the problem which occurs is that the current bond yield is unknown. Therefore, we must predict them in a prior step, i.e. we construct the bond yield with the fully nonparametric model

\[
b_t = p(w_{t-1}) + \zeta_t,
\]

(3)

where \( p \) is an unknown function, \( w_{t-1} \) is a vector of explanatory variables as for example, lagged interest rates or bond yields, and \( \zeta_t \) an error. In our empirical study we find evidence for the use of a first-order auto-regression in model (3), justified by a test for long-run memory that is robust to short-range dependence, see Lo (1991). Both, model (2) and (3), are estimated with a local linear kernel smoother using cross validation. For the choice of the bandwidth, we basically have two possibilities. Either we treat each model separately, determining first the best (in terms of \( R^2_V \)) bond model and using this in the second step, or we choose the bandwidth in both steps according to the best \( R^2_V \) for the stock return.
prediction.

As discussed, not only economic intuition motivates the inclusion of the constructed bond yields but also statistical arguments. In Theorem 3.7 we will develop the mathematical justification for the use of constructed variables in the case of dependent data. In other words, when we estimate nonparametrically stock returns using a generated regressor, we asymptotically obtain the same function as if we had observed the real bond yield. Basically, the bias of the final estimate is enlarged by an additive factor which is proportional to the bias of the predicted variable from the first step. A similar relationship holds for the variance which is increased by an additive term proportional to the variance of the constructed regressor. This relates the bond to the stock prediction. For simplification ignore for a moment $v_{t-1}$ in (2), and call the function containing the real bonds $\tilde{g}$. A closer look to the prediction error $\varepsilon_t$ gives

$$Y_t - g(\hat{b}_t) = [Y_t - \tilde{g}(\hat{b}_t)] + [\tilde{g}(\hat{b}_t) - \tilde{g}(\hat{b}_t)] + [\tilde{g}(\hat{b}_t) - g(\hat{b}_t)]$$

$$\approx \tilde{\varepsilon}_t + \tilde{g}'(\xi)(\hat{b}_t - \hat{b}_t).$$

The last term in (4) vanishes as we will see in Theorem 3.7 and the second term can be easily approximated. The gain in our two-step procedure comes now from the fact that the bond in the second term in (5) is quite predictable. We confirm this fact in the empirical part 4.2 (see Table 2). In the same vain, Lin et al. (2014) find that bond returns are more predictable then stock returns. Another idea would be the following: first, estimate $g$ with the available bond data $b_{t-1}$, and second, evaluate $\hat{g}$ at the constructed $\hat{b}_t$. Since, however, this procedure did not improve the stock forecasts, we skip it from further considerations.

One could directly use the variables in the vector $w_{t-1}$ as regressors in model (2). But the model would suffer from complexity and dimensionality in several aspects: The dimension of the covariates as well as their interplay. In the nonparametric literature, typically two strategies are proposed to circumvent these problems—either semiparametric modeling or additivity, both to import structure.
(2003) showed that additive models fail to improve the prediction of stock returns due to a non-ignorable interaction between the predictors. We improve these results by providing additional structure which is inherit by the underlying data generating process. We think of the same years bond yield as an important factor which captures some of the relevant features for the expected stock returns. Then, the inclusion of bond yields when predicting stock returns nonparametrically acts as a kind of complexity and dimension reduction due to the import of more structure.

To see if it is possible to further improve the predictive power in our setting, we will also analyse the model (2) with a different dependent variable. We consider the ratio between current stock returns and dividend yield, i.e. $Y^*_t = Y_t/d_t$ (see Section 4).

3. Mathematical justification

We prove the consistency of a function estimate which makes use of constructed variables and derive its asymptotic properties. For the prediction in the time series context, we follow the steps from Ferraty et al. (2001) and combine them with Sperlich (2009). Let us consider a sample of real random variables $\{(X_i, Y_i), i = 1, \ldots, n\}$ which are not necessarily independent and want to estimate the unknown function $m(x) = E(Y|X = x)$, $x \in \mathbb{R}$, that should always exist. Note that for time series $\{(Z_i), i \in \mathbb{N}\}$ a $k$-step ahead forecast is included in a natural way setting $Y_i = Z_{i+k}$ and $X_i = Z_i$. We concentrate only on the case of an auto-regression function of order one. Since we face constructed realisations for $X$, we assume a predictor with an additive bias and a stochastic error:

$$\hat{x} = x + b(x) + u(x) \quad (6)$$

\footnote{For more technical details of the proofs we refer to the appendix.}

\footnote{We don’t specify a particular one but we will need some assumptions on it. The used sample of size $N$, for instance, consists of some instruments $Z \in \mathbb{R}^3$. In the following, we have $N=n$, since we use the same series in both the prediction and final step.}
uniformly, where \( u(x) := u \cdot \sigma_u(x) \). The independent random variables \( u \) are normalised versions of \( u(x) \). The conditional variance at point \( x \) is \( \sigma_u(x) \). This is rather general as it holds for almost all common predictors. For technical reasons, we further assume finite higher moments for \( u \). Then, for example the Nadaraya-Watson estimator is

\[
\hat{m}_{NW}(x) = \hat{q}(x) \frac{f(x)}{\hat{f}(x)},
\]

with \( \hat{f}(x) = \frac{1}{nh} \sum_{i=1}^{n} K \left( \frac{\hat{X}_i - x}{h} \right) \) and \( \hat{q}(x) = \frac{1}{nh} \sum_{i=1}^{n} Y_i K \left( \frac{\hat{X}_i - x}{h} \right) \)

where \( K \) denotes some kernel function with bandwidth \( h \).

To measure the strength of dependence in the time series, we limit us to the strong- or \( \alpha \)-mixing\(^4\) defined in Doukhan (1994) or Fan and Yao (2003) as \( \lim_{n \to \infty} \alpha(n) = 0 \), for the mixing coefficient

\[
\alpha(n) = \sup_{A \in \mathcal{F}_n^\infty, B \in \mathcal{F}_n^\infty} |P(A)P(B) - P(AB)|,
\]

where \( \mathcal{F}_i^j \) is the \( \sigma \)-algebra generated by \( \{X_k, i \leq k \leq j \} \). We further assume that the sequence \( \{(X_i, Y_i), i = 1, \ldots, n\} \) is algebraic \( \alpha \)-mixing, i.e. that for some real constants \( a, c > 0 \) we have \( \alpha(n) \leq cn^{-a} \). To get the asymptotic properties in the context of strong mixing, we make use of an exponential inequality of the Fuk-Nagaev type, cf. Rio (2000).

**Lemma 3.1.** For an algebraic \( \alpha \)-mixing sequence of random variables \( \{(Z_i), i \in \mathbb{N}\} \), with \( s_n^2 = \sum_{i=1}^{n} \sum_{j=1}^{n} |\text{cov}(Z_i, Z_j)| \) and \( ||Z_i||_\infty < \infty \) for all \( i \), holds for some \( \varepsilon > 0 \) and \( r > 1 \)

\[
P \left( \left| \sum_{i=1}^{n} Z_i \right| > 4 \varepsilon \right) \leq 4 \left( 1 + \frac{\varepsilon^2}{r s_n^2} \right)^{-\frac{5}{2}} + 2ncr^{-1} \left( \frac{2r}{\varepsilon} \right)^{a+1}.
\]

Furthermore, we need the Billingsley inequality from Bosq (1998) to bound from above the covariance of two elements of a strong-mixing time series.

**Lemma 3.2.** For an \( \alpha \)-mixing sequence of random variables \( \{(Z_i), i \in \mathbb{N}\} \), with \( ||Z_i||_\infty < \infty \) for all \( i \neq j \), holds \( |\text{cov}(Z_i, Z_j)| \leq 4 ||Z_i||_\infty ||Z_j||_\infty \alpha(|i - j|) \).

To prove the asymptotic behaviour of the kernel regression estimator (7), we make some common

\(^4\)The weakest of the usually defined mixing conditions.
assumptions. As noted above, we analyse an algebraic $\alpha$-mixing sequence of real random variables $\{(X_i, Y_i), i = 1, \ldots, n\}$. We suppose that for all $i \neq j$ the joint density $f_{ij}$ for the pair $(X_i, X_j)$ exists and that $|Y| < C < \infty$ almost surely. Also for the unobservables $X_i$, we assume a density function $f_X$ which is bounded and has a continuous second derivative. At the fix $x \in \mathbb{R}$ we suppose $f_X(x) > 0$. Let the kernel $K$ be integrable, bounded, with compact support and continuous second derivative. It fulfils $\int K(s)ds = 1$ and $\int sK(s)ds = \int K'(s)ds = \int K''(s)ds = 0$. For both, the deterministic and the stochastic part of the predicted realisations $\hat{x}$ in (6), we assume that $b(x)$ and $b'(x)$ are at least of order $O(h_0^2)$ uniformly, and $\sigma_u^2(x)$ of order $O((nh_0^\delta)^{-1})$. Here, $h_0$ is a smoothing parameter tending to zero when the sample size $n$ goes to infinity and $\delta$ refers to the dimension of the used instruments in the prediction step. Let further be $b(\cdot)$ and $\sigma_u(\cdot)$ Lipschitz-continuous. To simplify our calculations, we further suppose that $h_0^2h^{-1}$ and $(nh_0^\delta h)^{-1}$ go to zero, and use the usual assumption that $nh$ and $nh_0^\delta$ go to infinity as $n \to \infty$.

Before we state the main result of the section, we collect some important facts. First, we define the following variables for $l \in \{0, 1\}$

$$Z_i = Y_l^i K\left(\hat{X}_i - \frac{x}{h}\right) - E\left[Y_l^i K\left(\hat{X}_i - \frac{x}{h}\right)\right]$$

and analyse the asymptotic behaviour of

$$s_n^{2*} = \sum_{i=1}^n \sum_{j \neq i} |\text{cov}(Z_i, Z_j)|.$$

**Proposition 3.3.** Under the above assumptions holds $s_n^{2*} = o(nh) + O(n^2\alpha(\tilde{\Delta}))$, where $\tilde{\Delta}$ has the same order like the slowest from $\left\{ \frac{1}{h \log n}, \frac{n h_0^\delta h}{\log n}, \frac{(nh_0^\delta h)^2 h}{\log n} \right\}$.

When $(nh_0^\delta)^{-1} = O(h^2)$ the above proposition reduces to $s_n^{2*} = o(nh) + O(n^2\alpha((h \log n)^{-1}))$ as in the case without any prior prediction, i.e. $b(x) = \sigma_u(x) = 0$.

**Proposition 3.4.** Under the given assumptions and if exists an $\varepsilon > 0$ such that

$$\Delta^{a-1} = O(n^{-1-\varepsilon}),$$

12
with \( \Delta \) from \( \{ h, (nh_0^2)^{-1}, (nh_0^3)^{-1} \} \), it holds that \( s_n^2 = o(n\Delta) \).

**Proposition 3.5.** Under the assumptions of Proposition 3.4 we have \( \text{var}(Z_1) = O(\Delta) \).

With \( \Delta \) from Proposition 3.4 we can directly conclude

\[
s_n^2 = \sum_{i=1}^{n} \sum_{j=1}^{n} |\text{cov}(Z_i, Z_j)| = n \cdot \text{var}(Z_1) + s_n^2 = O(n\Delta). \tag{10}
\]

Before we specify the result about the convergence of estimator (7) we need

**Proposition 3.6.** Under the assumptions and \( \Delta \) from Proposition 3.4, verifying

\[
c_1n^{2+\theta} \leq \Delta \leq c_2n^{1-\theta}, \tag{11}
\]

with existing \( c_1, c_2, \theta > 0 \), it holds for \( \nu \) and \( \epsilon > 0 \) with \( \psi = g \) or \( \psi = f \)

\[
P \left( \left| E\dot{\psi}(x) - \dot{\psi}(x) \right| > \epsilon \sqrt{\frac{\log n}{nh^{2}}} \frac{\Delta}{\epsilon} \right) = O(n^{-1-\nu}). \tag{12}
\]

Now we can state the main theorem. For continuous (around \( x \)) functions \( m \) and \( f \) we get the quasi complete convergence\(^5\) of Nadaraya-Watson estimators with constructed regressors.

**Theorem 3.7.** Under the above assumptions and (11), it holds quasi completely that \( |\hat{m}_{NW}(x) - m(x)| \longrightarrow 0 \).

The extension to the local linear estimator is almost straightforward. For \( j = 0, 1, 2 \)

\[
s_j(x) = \sum_{i=1}^{n} K \left( \frac{\hat{X}_i - x}{h} \right) (\hat{X}_i - x)^j \quad \text{and} \quad t_j(x) = \sum_{i=1}^{n} K \left( \frac{\hat{X}_i - x}{h} \right) (\hat{X}_i - x)^j Y_i,
\]

we can define \( \hat{m}_{LL}(x) := (t_0(x)s_2(x) - t_1(x)s_1(x))/(s_0(x)s_2(x) - s_1^2(x)) \) what leads to

\[
\hat{m}_{LL}(x) = \frac{\sum_{i=1}^{n} C \left( \frac{\hat{X}_i - x}{h} \right) Y_i}{\sum_{i=1}^{n} C \left( \frac{\hat{X}_i - x}{h} \right)}, \tag{13}
\]

with \( C \left( \frac{\hat{X}_i - x}{h} \right) = \sum_{j \neq i} K \left( \frac{\hat{X}_i - x}{h} \right) (\hat{X}_j - \hat{X}_i) K \left( \frac{\hat{X}_j - x}{h} \right) (\hat{X}_j - x) \) as a discretisation of \( C(u) = \int K(u - v)vK(u)vdv \). Since equation (13) is of the same form like (7) and the kernel \( C \) fulfills the same conditions.

\(^5\)For a sequence of real random variables \( X_n \) exists a real random variable \( X \) such that for all \( \epsilon > 0 \) holds \( \sum_{i=1}^{\infty} P(\|X_i - X\| > \epsilon) < \infty \), cf. Serfling (1980).

\(^6\)Note that \( C \) is a bimodal kernel. Since it puts more weight to points close to \( x \), except if they are too close, than to points far from \( x \), it is a natural choice in the case of strong mixing data, see Kim et al. (2009).

as $K$, the application of Theorem 3.7 yields

**Corollary 3.8.** Under the assumptions of Theorem 3.7, it holds quasi completely that $|\hat{m}_{LL}(x) - m(x)| \rightarrow 0$.

For mean square convergence, asymptotic normality and higher order polynomials, one could directly extend the work of Masry and Fan (1997) to the case of predicted regressors.

4. **Empirical evidence and simulation studies**

We interpret our method presented as a two stage regression approach. Based on the idea that the bond of the same year captures an important part of the stock return we search in the first step the optimal prediction model for the bond. Afterwards, as we have seen in Theorem 3.7, we can consistently predict stock returns using the predicted bond yields.

4.1. **Data description**

Consider the annual Danish stock and bond market data for the period 1923 – 1996 from Lund and Engsted (1996). In the appendix of their work, a detailed description of the data can be found. We use a stock index based on a value weighted portfolio of individual stocks chosen to obtain maximum coverage of the market index of the Copenhagen Stock Exchange (CSE). Notice that the CSE was open during the second world war. When constructing the data, corrections were made for stock splits and new equity issues below market prices. Table 1 presents summary statistics of the available variables.
the following, we use the dividend price ratio, $d$, the stock return, $S$, the long-term interest rate, $L$, the short-term interest rate, $r$, and the bond yields, $b$, as explanatory variables.

4.2. The prior step: A simple bond yield predictor

We speak of a simple predictor as in the literature quite complex models can be found for this problem. Our main target, however, are the stock returns where bond yield prediction is just an auxiliary step in order to reduce complexity and dimension. Therefore, the model and bandwidth selection for (3) has to be based on the objective of maximising the $R^2_V$ of the stock return problem (2). Recognising that the model that maximises the $R^2_V$ for bond prediction is not necessarily the one that maximises the $R^2_V$ for stock returns, it becomes clear that it is worth to consider nonparametric alternatives for (3), even if parametric models seem to do a very good job for bond yield prediction alone. This is the reason why we need Theorem 3.7; for parametric predictors $\hat{x}$ the consistency of (7) follows trivially.

If we just look at the bond yield prediction, then we get mostly positive $R^2_V$ for the models listed in Table 2. We observe that only in few cases a local linear predictor does a better job than a linear model as far as we look at the $R^2_V$ for bond yields. The interesting numbers, however, we will see only when looking at the $R^2_V$ for stock returns in Table 3, next section.

Figure 1 shows the estimated functions $\hat{p}$ for the bond yield prediction step with a single covariate $w_{t-1}$ from the set \{S, r, d, L\} using a linear model (triangles) and a fully nonparametric model (diamonds). For some of the models a clear nonlinear behavior can be observed. Figure 2 displays the estimation results of the combination of the variables $r, b$ that gives the largest validated $R^2_V$ value for 2-dim. models in Table 2, again for the linear model (triangles) and the fully nonparametric model (diamonds). Note that we set one variable at a certain level (25%, 50%, 75% quantile) and plot the relationship of bond

yields with the remaining variable. For example, on the left-hand side of Fig. 2, we set the lagged bond yield at values of 2.0, 5.7, and 12.2. The linear model and the fully nonparametric model behave very similar (what is not surprising, since both have more or less the same validated $R^2$ value). Only at the boundaries a clear difference of both models is visible. Note again that we are interested in stock return prediction and that the predicted bond used in the final step not necessarily has to be the best possible one.
Figure 2: Estimated function \( \hat{p} \) for bond yield prediction with lagged bond yield and risk-free rate as covariates \( w_{t-1} \): Left: at 25%, 50%, 75% quantile level for lagged bond yield, Right: at 25%, 50%, 75% quantile level for lagged risk-free rate; Estimated with: linear model (triangles), fully nonparametric model (diamonds)
4.3. Stock prediction

Now we examine the predictive relationship of excess stock returns $Y_t$ and a set of financial variables $v_{t-1}$ using different models. Results of this exercise are summarised in Table 3. First, for the sake of illustration, we develop our strategy step by step and start with the estimation of the model $Y_t = g(v_{t-1}) + \varepsilon_t$ with a fully nonparametric kernel based method as well as the parametric counterpart (not including the constructed bond yield $\hat{b}_t$). Part (a) of Table 3 reports the results and shows that all parametric models produce negative validated $R^2_V$ values. It means that with a linear regression approach we cannot better forecast one-year stock returns than the simple mean. A more sophisticated technique is needed. In fact, our so far best nonparametric model\(^7\) uses actual lagged bond yields, $b_{t-1}$, and gives an $R^2_V$ of 5.9%. But even better results are possible when we include the generated bond yield $\hat{b}_t$ in our analysis.

Second, we follow our procedure proposed in Section 2 and generate the current bond yield with model (3). Then we include this constructed variable as a regressor in the final step, the model for excess stock returns as stated in equation (2). Let us do this first without any further regressor $v_{t-1}$. As discussed before, we have to choose the model and bandwidths along the largest $R^2_V$ value for predicting stock returns\(^8\). How much the predictive power has increased by this method can be seen when comparing part (a) with part (b) of Table 3. The best model in (b) uses as single regressor lagged bond yields in the first step and only the predicted bond as covariate in the second step ($R^2_V$ of 10.6%). Even for the parametric counterpart our strategy helps to improve prediction power since we can observe positive $R^2_V$ for some models. As one can clearly see, the nonparametric version produces better results, recall our discussion in the previous section.

\(^7\)Nielsen and Sperlich (2003) report in an analog setting a $R^2_V$ value of 5.5 for a fully nonparametric two-dimensional model with dividend-price ratio, $d_{t-1}$, and lagged excess stock returns, $S_{t-1}$, as explanatory variables, but don’t use bond yields in their analysis.

\(^8\)If one chooses for example the bandwidth that predicts best bond yields in the prior step, then the values in Table 3 will shrink or remain the same. The best prediction model will still be $g(\hat{b}_t)$ but with an $R^2_V$ value of 9.0% instead of 10.6%.

</table>

Performance of nonparametric and parametric estimators for excess stock return predictions on different covariates: (a) Without constructed bond $\hat{b}_t$; (b) With $\hat{b}_t$ as unique regressor, constructed with variables $v_{t-1}$; (c) With $\hat{b}_t$ and the same variables $v_{t-1}$ as in the first bond prediction step. Bandwidth choice in the final step.

Third, we construct the current bond as before but accompany this regressor in model (2) by any combination of lagged variables from the predictor set \{d, S, L, r, b\} as our vector $v_{t-1}$. Then, the two largest $R^2_V$ were achieved by $g(\hat{b}_t, d_{t-1}, S_{t-1}, L_{t-1})$ where $\hat{b}_t = \hat{p}(d_{t-1})$ (yielding $R^2_V = 30.3\%$) or $\hat{b}_t = \hat{p}(d_{t-1}, L_{t-1})$ (yielding $R^2_V = 28.9\%$), respectively. Note that for an increasing set of regressor variables the corresponding multidimensional bandwidth grid on which we looked for the best predicting one had to be reduced for numerical reasons. Consequently, lower dimensional models have the tendency to be slightly favoured in our study. The full set of results for the 25 times 25 combinations of \{d, S, L, r, b\} is not shown for the sake of presentation, but available on request. We include in part (c) of Table 3...
only the ‘diagonal’ of those results since the predictive power is among the best of all possible models. In other words, in part (c) of Table 3 holds \( w_{t-1} = v_{t-1} \), exactly the same regressors used for the bond construction in step one accompany \( \hat{b}_t \) again in the second step. For completeness, also the results of the parametric counterpart are included in part (c) of Table 3. We see that our new prediction procedure improves the predictive power for stock returns. We find again convincing evidence that the two nonparametric steps are better than the parametric counterpart. For the best model in Table 3 – we have \( w_{t-1} = v_{t-1} = (d_{t-1}, L_{t-1}) \) – we find a large increase in the \( R^2_V \) value from 5.9% to 28.3%, an about factor five improvement compared to the best model without constructed bonds. This finding again indicates that the bond captures a quite important part of the stock return which is related to the change in long-term interest rate.

Figure 3 shows the estimated functions \( \hat{g} \) for the excess stock return predictions based on a single covariate from the set \( \{S, r, d, b\} \) using a fully nonparametric model (diamonds), a fully nonparametric model with the constructed bond as single regressor in the second step (crosses), and a fully nonparametric model based on the predicted bond together with the regressor of the first step (pluses). Again, for some of the models a clear nonlinear pattern can be observed. Figure 4 displays the estimation results of the combination of the variables \( d, L \) that gives the largest validated \( R^2 \) value in Table 3, again for three different models used in Figure 3. Note that we set one variable at a certain level (25%, 50%, 75% quantile) and plot the relationship of excess stock returns with the remaining variable. For example, on the left-hand side of Fig. 4, we set the lagged long-term interest rate at values of 5.1, 6.4, and 10.6. It seems that the model which uses only the predicted bond as a covariate is too inflexible in its functional form and needs the additional information which is still inherent in the covariates of the first step when it comes to stock return prediction in step 2. This underlines the findings of Table 3 where the largest validated \( R^2 \) values can be found in part (c) for the nonparametric estimators of the models based on the predicted bond together with the same covariates of the first step.
Figure 3: Estimated function $\hat{g}$ for excess stock return prediction with different covariates. Upper panel: excess stock returns, risk-free rate; Lower panel: dividend by price, bond yield; Estimated with: fully nonparametric model (diamonds), predicted bond as single regressor in the second step (crosses), predicted bond together with the regressor of the first step (pluses)
**Figure 4:** Estimated function $\hat{q}$ for excess stock return prediction with lagged dividend by price and long-term interest rate as covariates: Left: at 25%, 50%, 75% quantile level for lagged long-term interest rate, Right: at 25%, 50%, 75% quantile level for lagged dividend by price; Estimated with: fully nonparametric model (diamonds), predicted bond as single regressor in the second step (crosses), predicted bond together with dividend by price and long-term interest rate in second step (pluses)
In order to get a better view of the potential of our proposed method, we analyze the out-of-sample mean-squared error (oos-mse) for a one-step ahead prediction with an expanding estimation sample for the new method in comparison to the oos-mse of the corresponding fully nonparametric and linear models as well as the historical mean. For an illustration we use dividend by price and long-term interest rate since we observed for this combination of covariates the largest $R^2$ in Table 3. Figure 5 shows the predicted annual excess stock returns of the different models in comparison to the realized annual excess stock returns of the CSE. We observe the smallest oos-mse for the new method (0.044), followed by the historical mean (0.049), the linear model (0.058), and the fully nonparametric model (0.059).

The last part of our empirical study concentrates on the change of the dependent variable. Up to now, we used the excess stock return but for the following we divide this value by the dividend yield, i.e. we use $Y_t^* = Y_t/d_t$. Table 4 summarises our findings for $Y^*$.

**Table 4:** $R^2_V$-values (in percent) for model (2) with $Y_t^* = Y_t/d_t$ as dependent variable.

First line: fully parametric model, second line: nonparametric estimation without constructed bond, third line: nonparametric with constructed bond and bandwidth selection in the final step.

The first line refers again to the parametric version of model (2) and the second line to the fully nonparametric method, both without constructed bonds. Almost all of the parametric models have negative $R^2_V$ values and also only a small number of nonparametric models beat the simple mean. In contrast, when we include the constructed bond in the nonparametric prediction, a large increase of the validated $R^2_V$ can be observed. For example, the model which uses long- and short-term interest rate, and lagged bond yields for both the bond generation and following stock prediction, has a $R^2_V$ value (43.5%) that is over three and a half times larger than the value of the best model without constructed bonds (12.3%).

Note: For simplicity’s sake we use \(\sigma_{s_1} = \sigma_{s_2} = \sigma_m\) and refer to it as \(\sigma\). Averaged values over 500 simulation runs with standard errors in brackets. Left panel: \(n=50\), right panel: \(n=200\).

4.4. Simulation studies

A simulation study gives us the possibility to highlight the potential of our method. We first show the effects of a dimension reduction and afterwards of a pronounced curvature.

Let us consider a four dimensional function that is separable into two terms: 

\[ m(x_1, \ldots, x_4) = \tilde{m}(s_1, s_2) \]

with \(s_1 = s_1(x_1, x_2)\) and \(s_2 = s_2(x_3, x_4)\). We simulated data from the following models: 

\[ S_1 = x_1 + x_1 x_2 + \varepsilon_{s_1}, \quad S_2 = \exp(x_3 + x_4) + \varepsilon_{s_2}, \quad \text{and} \quad Y = m(x_1, \ldots, x_4) + \varepsilon_{s_m} = \tilde{m}(s_1, s_2) + \varepsilon_{s_m} = s_1 + s_2 + \varepsilon_{s_m}. \]

For each explanatory the support is [0, 1]. An autoregressive design with \(\phi = 0.75, 0.2, 0.02\) for \(x_1, \ldots, x_3\) was used; also a normal for \(x_4\). Different parameter values \(\sigma\) for the zero mean normal error distributions were investigated as well as different sample sizes \(n\). The kernel used was the Gaussian. For computational reasons the bandwidths are chosen separately in each step of the simulation. In step one we predict \(s_1\) and \(s_2\), used in step 2 to estimate function \(\tilde{m}\).

Lines three and four of Table 5 present the results for the two-step approach for \(\tilde{m}\) and the fully nonparametric method estimating \(m\) in terms of \(R^2_V\) values, averaged over 500 runs. The proposed two-step procedure succeed in improving on the fully nonparametric estimator in all cases by far. The effect of the dimension reduction is of course more pronounced for the smaller sample size and results in an almost factor 2 improvement.

\(^{9}\text{Note that this is again suboptimal, i.e. a bandwidth choice along the final objective would give even better results for our method than those presented in Table 5.}\)

Note: Averaged values over 500 simulation runs with standard errors in brackets. Sample size: n=50. Left panel: $\sigma_s = 0.1$, middle panel: $\sigma_s = 0.3$, right panel: $\sigma_s = 0.5$.

For the second part we consider the function composition $m(x) = \tilde{m} \circ s(x)$, where the inner function $s$ has a pronounced curvature. We simulated data from the following models: $S = \sin(4\pi(x - 1/8)) + \cos(4/3 \cdot \pi(x - 1/2)) + 1.6 + \varepsilon_{\sigma_s}$ and $Y = m(x) + \varepsilon_{\sigma_m} = \sin \circ s(x) + \varepsilon_{\sigma_m}$, i.e. $\tilde{m}(x) = \sin(x)$. Note that $s$ is one of the example functions used in Park et al. (1997). A uniform design was used with the support $[0,1]$. Different parameter values $\sigma$ for the zero mean normal error distributions were investigated for a sample size of $n = 50$. The kernel used was the Gaussian and the bandwidths are chosen separately in each step for the two-step part. Again we are aware of the suboptimality, i.e. we could even do better with respect to the $R^2_V$ but at the cost of computing time. Table 6 reports the results. We find that already in this simple example the proposed two-step approach can help to obtain clearly better results, i.e. much larger $R^2_V$-values in all cases. Figure 6 shows the used inner function (left) and estimates of $m$ and $\tilde{m}$ (right). We see that our method can better estimate problematic regions, in particular by bias reduction.

5. Concluding remarks and outlook

Motivated by economic theory and statistical arguments, we include the same years bond yield in the fully nonparametric prediction approach for excess stock returns. Since the current bond yield is unknown, we propose to construct it in a prior step using again nonparametric techniques. The bandwidths should be chosen in such a way that they maximise the $R^2_V$ of the final step. The empirical study demonstrates that this two-step approach can improve the stock return prediction enormously. We moreover prove the
Figure 6: Left: Simulated Data (dots) with $\sigma_s = 0.3$ from inner function $s$ (solid), first-step estimate (dashed); Right: Simulated Data (dots) with $\sigma_m = 0.3$ from function composition $m$ (solid), two-step estimate (dashed), usual nonparametric estimate (dotted)

consistency of our method and derive the asymptotic behaviour of our final predictor. We illustrate the improvement due to our method using annual Danish stock and bond market data which were studied in detail in former articles by different authors. Our results confirm our motivation of including the same years bond yield, namely that it captures the most important part of the stock return, that one related to the change in long-term interest rate. This actually holds not only for stock returns but also for transformed variables, as for example returns divided by dividend yields.

The statistically insights are the following. It is clear that we face a regression model that exhibits high complexity and dimensionality. An obvious remedy would be the imposing of structure. Since it has been shown that additive separability is inappropriate because of unknown interactions, we make use of financial theory to exploit the inherit structure of stock returns. Alternatively, one could interpret the first stage as an optimal nonparametric transformation that maps, for example, the long-term interest rate to the current bond yield, $L_{t-1} \rightarrow \hat{b}_t$. The subsequent nonparametric smoother of the transformed variable is than characterised by less bias. Here, we present a practical example in the spirit of the somewhat theoretical method proposed by Park et al. (1997) which improves nonparametric regression
with transformation techniques. Although we extend their method in several aspects, their paper provides some statistical intuition for the success of our approach. Our simulations additionally underpin the key idea of complexity and dimension reduction.

### Appendix A. Proofs

**Proof of Proposition 3.3.** Since the variables $Z_i$ in (8) are centered, we calculate for $i \neq j$

$$|EZ_i Z_j| = |EY_i^t Y_j^t K\left(\frac{\hat{X}_i - x}{h}\right) K\left(\frac{\hat{X}_j - x}{h}\right) - EY_i^t K\left(\frac{\hat{X}_i - x}{h}\right) EY_j^t K\left(\frac{\hat{X}_j - x}{h}\right)|. \quad (A.1)$$

First, we analyse the second term in the last equation and use the assumption that all $Y_i$ are bounded.

$$EY_i^t K\left(\frac{\hat{X}_i - x}{h}\right) \leq C \int \int K\left(\frac{u - x + b(u) + v\sigma(u)}{h}\right) f(u, v) dudv.$$

A simple Taylor-expansion of the kernel leads to

$$C \int \int \left\{ K\left(\frac{u - x}{h}\right) + K'\left(\frac{u - x}{h}\right) \frac{b(u) + v\sigma(u)}{h} + K''\left(\frac{u - x}{h}\right) \frac{b(u) + v\sigma(u)^2}{2h^2} \right\} f(u, v) dudv,$$

where $\kappa \in (0, 1)$. With the common substitution $s = (u - x)h^{-1}$ we get

$$EY_i^t K\left(\frac{\hat{X}_i - x}{h}\right) = O(h + (nh_0^6 h)^{-1}).$$

Analog steps lead to

$$E \left[ Y_i^t Y_j^t K\left(\frac{\hat{X}_i - x}{h}\right) K\left(\frac{\hat{X}_j - x}{h}\right) \right] = O(h^2 + (nh_0^6 h)^{-1} + (nh_0^6 h)^{-2}),$$

and thus the covariance $|\text{cov}(Z_i, Z_j)|$ for $i \neq j$ is of the same rate.

On the other hand, we can directly make use of Lemma 3.2 because all $Y_i$ and $K$ are bounded so that $||Z_i||_\infty < \infty$. It follows

$$|\text{cov}(Z_i, Z_j)| \leq C \alpha(|i - j|).$$

The idea is now to combine both results. When the indices of the two variables $Z_i$ and $Z_j$ are close\(^{10}\) to each other we use the first one, and when they are far from each other the second one. To control this,

\(^{10}\)Since we use time series data, this means that the two events are close in time.
we introduce a sequence of integers $a_n$ and obtain

$$s_n^{2*} = \sum_{i=1}^{n} \sum_{j \neq i} |\text{cov}(Z_i, Z_j)|$$

$$\leq C \left( \sum_{0 < |i-j| \leq a_n} \{h^2 + (nh_0^\delta)^{-1} + (nh_0^\delta h)^{-2}\} + \sum_{|i-j| > a_n} \alpha(|i-j|) \right).$$

Since $i \neq j$, the largest possible term for $a_n$ is $0 < |i-j| \leq a_n \equiv n - 1$ and the smallest $|i-j| > a_n \equiv 1$. Furthermore, the maximum number of elements in $s_n^{2*}$ is $n^2 - n$, and we obtain for $\Delta$ that is of the same order like the slowest term in $O(h^2 + (nh_0^\delta)^{-1} + (nh_0^\delta h)^{-2})$

$$\sum_{0 < |i-j| \leq a_n} \Delta \leq \frac{n^2 - n}{n(n-1)} \iff \sum_{0 < |i-j| \leq a_n} \Delta = O(\Delta a_n)$$

and

$$\sum_{|i-j| > a_n} \alpha(|i-j|) \leq \frac{n^2 - n}{n^2} \iff \sum_{|i-j| > a_n} \alpha(|i-j|) = O(n^2 \alpha(a_n)).$$

This means that

$$s_n^{2*} = O\left(\{h^2 + (nh_0^\delta)^{-1} + (nh_0^\delta h)^{-2}\}na_n + n^2 \alpha(a_n)\right).$$

Choosing $a_n$ from \( \left\{ \frac{1}{h \log n}, \frac{nh_0^\delta h}{\log n}, \frac{(nh_0^\delta h)^2 h}{\log n} \right\} \) proves the Proposition.

Proof of Proposition 3.4. Using the algebraic mixing condition and Proposition 3.3

$$s_n^{2*} = o(nh) + O(n^2 \Delta^{-a}),$$

with $\Delta$ from

$$\left\{ \frac{1}{h \log n}, \frac{nh_0^\delta h}{\log n}, \frac{(nh_0^\delta h)^2 h}{\log n} \right\}.$$

Using the assumption (9) and noting that $\left( \frac{\log n}{n^a} \right)^a \to 0$ for $n \to \infty$ closes the proof.

Proof of Proposition 3.5. We use again that $Y_1$ is bounded so that remains to analyse

$$E \left[ K \left( \frac{X_1 - x}{h} \right) \right]^2 = \int \int K \left( \frac{u - x + b(u) + v \sigma(u)}{h} \right)^2 f(u, v) dudv.$$

With a Taylor-expansion and analog steps like in the proof of Proposition 3.3 we get

$$= \int \int \left\{ K \left( \frac{u - x}{h} \right) + K' \left( \frac{u - x}{h} \right) \frac{b(u) + v \sigma(u)}{h} + K'' \left( \frac{u - x}{h} + \kappa \frac{b(u) + v \sigma(u)}{h} \right) \frac{(b(u) + v \sigma(u))^2}{2h^2} \right\}^2 f(u, v) dudv,$$
where \( \kappa \in (0, 1) \), and find that
\[
E \left[ K \left( \frac{\hat{X}_1 - x}{h} \right) \right]^2 = O(h + (nh^6 h^{-1} + (nh^6)^2 h^3)^{-1})
\]
what proves the Proposition.

Proof of Proposition 3.6. Using \( l = 0 \) for \( \psi = f \) and \( l = 1 \) for \( \psi = q \), respectively, we directly get with (8)
\[
|E \hat{\psi}(x) - \hat{\psi}(x)| = \left| E \left( \frac{1}{nh} \sum_{i=1}^{n} Y_i K \left( \frac{\hat{X}_i - x}{h} \right) \right) - \frac{1}{nh} \sum_{i=1}^{n} Y_i K \left( \frac{\hat{X}_i - x}{h} \right) \right|
= \frac{1}{nh} \sum_{i=1}^{n} \left( Y_i K \left( \frac{\hat{X}_i - x}{h} \right) - E \left( Y_i K \left( \frac{\hat{X}_i - x}{h} \right) \right) \right)
= \frac{1}{nh} \sum_{i=1}^{n} Z_i.
\]
Therefore, applying Lemma 3.1 we obtain
\[
P (|E \hat{\psi}(x) - \hat{\psi}(x)| > \delta) = P \left( \left| \sum_{i=1}^{n} Z_i \right| > nh\delta \right)
\leq 4 \left( 1 + \frac{\delta^2 n^2 h^2}{16rs^2} \right)^{-\frac{z}{2}} + 2ncr^{-1} \left( \frac{8r}{n\delta} \right)^{a+1}.
\]
Since we have seen in (10) that \( s_n^2 = O(n \Delta) \), with \( \Delta \) from Proposition 3.4, with \( \delta = \varepsilon \sqrt{\frac{\log n}{nh^2 \Delta}} \) we get
\[
P \left( |E \hat{\psi}(x) - \hat{\psi}(x)| > \varepsilon \sqrt{\frac{\log n}{nh^2 \Delta}} \right)
\leq 4 \left( 1 + \frac{\varepsilon^2 \log n}{16r} \right)^{-\frac{z}{2}} + 2ncr^{-1} \left( \frac{8r}{\varepsilon} \right)^{a+1} (n \Delta \log n)^{-\frac{a+1}{2}}.
\] (A.2)
Now, we can choose \( r > 1 \) such that \( \log n = o(r) \), and use the limit definition
\[
\exp(x) = \lim_{z \to \infty} \left( 1 + \frac{x}{z} \right)^z,
\]
with \( z = -r/2 \). For the first term of the right hand side of (A.2), we obtain for \( z \to \infty \)
\[
\left( 1 + \frac{\varepsilon^2 \log n}{16r} \right)^{-\frac{z}{2}} = \left( 1 - \frac{\varepsilon^2 \log n}{32z} \right)^z \to \exp \left( -\frac{\varepsilon^2 \log n}{32} \right) = n^{-\frac{\varepsilon^2}{32}}.
\]
Noting that \( C (\log n)^{-\frac{a+1}{2}} \leq C \) for \( n > 2 \) and a constant \( C \), (A.2) can be expressed as
\[
P \left( |E \hat{\psi}(x) - \hat{\psi}(x)| > \varepsilon \sqrt{\frac{\log n}{nh^2 \Delta}} \right)
\leq C n^{-\frac{\varepsilon^2}{32}} + C \varepsilon^{-(a+1)} n^{1 - \frac{a+1}{2}} r^a \Delta^{-\frac{a+1}{2}}.
\]
With \( r = n^b \) for \( b > 0 \), i.e. \( \log n = o(r) \), and the left hand side of the assumption (11),

\[
n^{1+ab-\frac{a+1}{2} \Delta - \frac{a+1}{2}} \leq n^{1+ab-\frac{a+1}{2} \cdot \frac{a+1}{2} - \theta^2 + \frac{a+1}{2}} = n^{-1-\theta^2 + ab} = n^{-1-\nu}.
\]

Thus, we obtain for a sufficiently small \( b \) that

\[
\begin{aligned}
P\left( |E\hat{\psi}(x) - \hat{\psi}(x)| > \varepsilon \sqrt{\frac{\log n}{nh^2}} \Delta \right) &\leq Cn^{-\frac{\varepsilon}{\xi^2}} + C\varepsilon^{-(a+1)}n^{-1-\nu}.
\end{aligned}
\]

Finally, for a sufficiently large \( \varepsilon \), we get that exist \( \nu, \varepsilon > 0 \) such that

\[
P\left( |E\hat{\psi}(x) - \hat{\psi}(x)| > \varepsilon \sqrt{\frac{\log n}{nh^2}} \Delta \right) \leq Cn^{-1-\nu},
\]

what proves the assertion.

**Proof of Theorem 3.7.** From Proposition 3.6 follows directly

\[
E\hat{q}(x) - \hat{q}(x) \rightarrow 0, \quad \text{and} \quad E\hat{f}(x) - \hat{f}(x) \rightarrow 0,
\]

both quasi completely. With the first part of the proof of Proposition 3.3 we obtain\(^{11}\)

\[
E\hat{f}(x) = \frac{1}{h} EK\left( \frac{\hat{X} - x}{h} \right) = f(x) + B_f(x) + o(h_0^2 + h),
\]

with \( B_f(x) = h^2/2f''(x)\mu_2(K) + \{b(x)f'(x) + b'(x)f(x)\}\mu_1(K') \), and thus

\[
E\hat{f}(x) - f(x) \rightarrow 0.
\]

The analog can be shown for \( E\hat{q}(x) \). With

\[
E\hat{q}(x) = \frac{1}{h} EYK\left( \frac{\hat{X} - x}{h} \right),
\]

and taking the conditional expectation for \( X = x \), we get

\[
E\hat{q}(x) = \frac{1}{h} \int \int m(u)K\left( \frac{u - x + b(u) + v\sigma(u)}{h} \right) f(u, v)dudv.
\]

Repeating the same steps as in the first part of the proof of Proposition 3.3, using \( q = m \cdot f \) as well as that the function \( q \) is continuous over the compact support of the kernel \( K \), i.e. that \( q(x + hs) \rightarrow q(x) \) uniformly in \( s \), we obtain

\[
E\hat{q}(x) - q(x) \rightarrow 0.
\]

Furthermore, from (A.4) and (12) follows the quasi complete convergence of \( \hat{f}(x) \) to \( f(x) \), i.e. for all

\(^{11}\)A similar result can be found in Theorem 2.1 (i) in Sperlich (2009).
\( \varepsilon > 0 \), it holds that
\[
\sum_{n=1}^{\infty} P(|\hat{f}(x) - f(x)| > \varepsilon) < \infty.
\]

Since \( f(x) > 0 \), we can define \( \delta = \varepsilon = f(x)/2 \) and get for \( \delta > 0 \)
\[
\sum_{n=1}^{\infty} P(\hat{f}(x) \leq \delta) < \infty. \tag{A.6}
\]

Note, that with (7) and \( q = f \cdot m \) we can state
\[
\hat{m}_{NW}(x) - m(x) = \frac{\hat{q}(x) - q(x)}{f(x)} + (f(x) - \hat{f}(x)) \frac{m(x)}{\hat{f}(x)}, \tag{A.7}
\]
and thus with (A.3) – (A.7) follows the assertion. \( \square \)
