Abstract. The present paper focuses on the numerical simulation of the interaction of laser-generated bubbles with a free surface, including comparison of the results with instances from high-speed videos of the experiment. The Volume Of Fluid (VOF) method was employed for tracking liquid and gas phases, while compressibility effects were introduced with appropriate equations of state for each phase. Initial conditions of the bubble pressure were estimated through the traditional Rayleigh Plesset equation. The simulated bubble expands in a non-spherically symmetric way, due to the interference of the free surface, obtaining an oval shape at the maximum size. During collapse a jet with mushroom cap is formed at the axis of symmetry, with the same direction as the gravity vector, which splits the initial bubble to an agglomeration of toroidal structures. Overall, the simulation results are in agreement with the experimental images, both quantitatively and qualitatively, while pressure waves are predicted both during the expansion and the collapse of the bubble. Minor discrepancies in the jet velocity and collapse rate are found and are attributed to the thermodynamic closure of the gas inside the bubble.

Keywords: Numerical simulation, compressible bubble dynamics, bubble interaction with free surface, interface capturing, cavitation

I. INTRODUCTION

The process of bubble growth and collapse is the core phenomenon in cavitating flows as it is linked to cavitation erosion. Indeed, it is well documented that the formation of jets in cavitating flows can contribute to cavitation erosion, due to the focused way of transferring energy from the bubble to the nearby walls ¹⁻³. Bubble growth and collapse in infinite liquid can be predicted using the Rayleigh Plesset equation ⁴; this equation is a simplified form of the Navier Stokes equations under the assumptions of spherical symmetry, incompressible liquid and negligible gas inertia inside the bubble¹. Over time, extensions of the original Rayleigh-Plesset version have been formulated, including e.g. compressibility effects, see the Plesset and Zwick variant ⁴ or model the presence of nearby bubbles, see the Kubota et al. modification ⁵. Unfortunately, the spherical symmetry assumption of the Rayleigh Plesset equation means that it cannot predict any jetting phenomena or other types of asymmetries in the bubble development arising from the local flow field/boundary configuration/forcing terms.

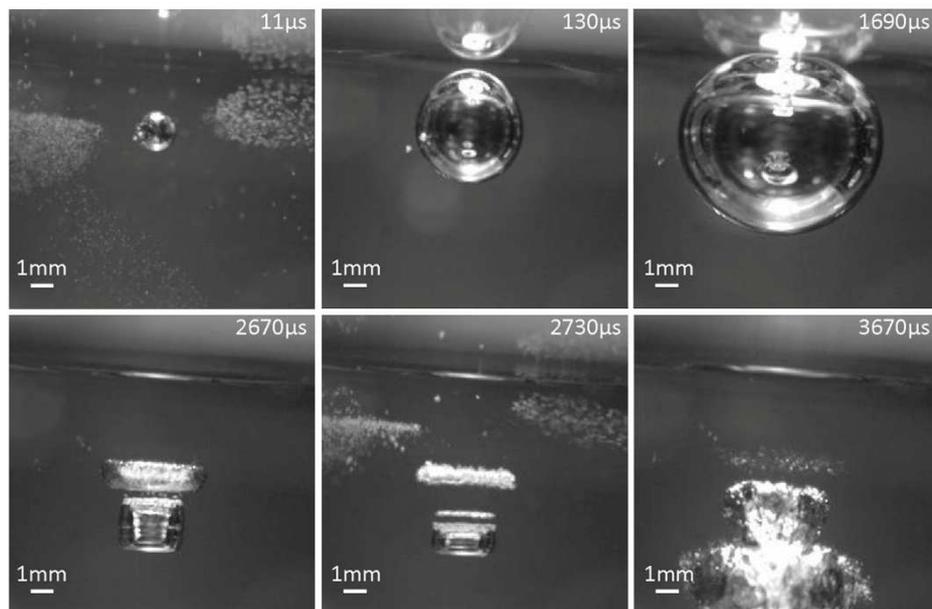

In order to capture the asymmetric bubble interface due to the presence of the aforementioned conditions, it is necessary to solve the potential flow equations, commonly done using the Boundary Element Method (BEM), or the 2D axis-symmetric/3D Euler/Navier-Stokes equations. BEM methods are commonly used when high accuracy bubble dynamics is required or when simulating bubble clusters see e.g. ^{6, 7}, however large deformations and topological changes of the bubble interface are somewhat problematic ⁸. On the other hand, the Euler or Navier-Stokes equations have to be solved with an interface tracking or interface capturing technique to describe the bubble interface. Such

^(a) Corresponding author, email: foivos.koukouvinis.1@city.ac.uk

46 works employ various techniques, from the Marker-and-Cell method of the pioneering work by
47 Plesset and Chapman ⁹, front tracking techniques by Hawker et al. ¹⁰, to Level-Set methodologies by
48 Lauer et al. ¹¹

49 In this work, the complicated interaction of a laser-generated bubble with the free surface of
50 initially stagnant water under earth gravity conditions is examined with CFD techniques. While
51 similar configurations have been simulated in the past with BEM (see for example, the work of
52 Robinson et al. ¹²), the flow has not been investigated beyond the topological transformation of the
53 initial bubble to a torus. In the present work, the bubble interface is captured with the Volume Of
54 Fluid (VOF) method, capable of describing topological changes of the interface. Compressibility
55 effects in both gas and liquid phases are included, since they are essential to explain the formation of
56 secondary bubbly structures. The aim of this work is to try to replicate the experiments that have been
57 conducted so far at EPFL ¹³ with CFD, show the level of agreement and potential room of
58 improvement in the models. To be more precise the main features that this work aims to replicate are
59 the following:

60 - Macroscopic flow evolution (qualitative): the initially spherical bubble deforms due to the
61 presence of the free surface, obtaining an oval shape, then collapses. During the collapse a jet is
62 formed at the top of the bubble, with a direction towards the bottom of the container, piercing the
63 bubble and breaking into two toruses. The whole process is shown in Figure 1; it is, in general, axis-
64 symmetric, with the axis of symmetry being the vertical axis passing through the centre of the bubble.
65 Only at the very last stages of the bubble rebound significant asymmetry develops, due to turbulence
66 and accumulation of various disturbances (shown later, at Figure 10).

67
68 Figure 1. Evolution of the bubble shape near the free surface. The free surface position is visible through the reflection.
69 Gravity acts towards the bottom of the figures. The white bar at the bottom left corner corresponds to 1mm length.
70

71 - The time evolution of the bubble size (quantitative). Since the bubble very quickly deforms in a
72 shape that is not a perfect sphere, two characteristic dimensions of the bubbly structures will be used
73 for the comparisons to follow: (a) the maximum distance from the axis of symmetry of the bubble in
74 the horizontal direction, which will be referred to as radius (b) the bubble extent at the vertical
75 direction, which will be referred to as height. Also, once the bubble breaks into two toruses the one at
76 the upper part, near the free surface, will be referred to as *torus 1* and the other, which is closer to the
77 bottom of the container, will be referred to as *torus 2* - see also Figure 2.

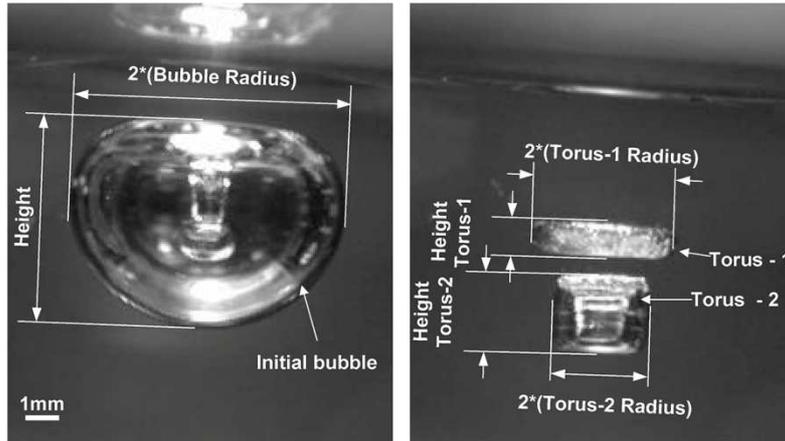

Figure 2. Bubble size naming convention that will be used hereafter and torus identification.

79
80
81

- Other geometric features of the bubble evolution (quantitative), that can be directly compared to the simulation, such as the jet diameter, maximum bubble radius etc.

84 The high-speed movies extracted from the experiment¹³ have a resolution of 400x250pixels, with a
85 scale of 17pixels corresponding to 1mm, so bubble dimensions can be derived.
86

87 II. EXPERIMENTAL SET-UP

88

89 A bubble collapsing near a free surface has experimentally been studied by Supponen et al.^{13, 14}
90 through high-speed imaging. In the experiment (details of the setup in¹⁴), a spherical cavitation
91 bubble is created in water contained in a cubic (18x18x18 cm³) test chamber using a green, high-
92 power laser pulse (wavelength 532 nm, duration 8 ns). The bubble is generated at distance of $s=2.95$
93 mm below the free surface. The bubble dynamics are visualised with a high-speed camera with speeds
94 up to 50 000 frames per second. The experiment is conducted at room temperature and at low pressure
95 (10.1 kPa=0.1 atm).
96

97 III. SIMULATION SET-UP

98

99 A. Geometry and computational mesh

100

101 The computational domain simulated is based on the dimensions of the test chamber that has been
102 used for parabolic flights in the past (see previous section, or¹⁵). We have chosen to proceed with 2D
103 axis-symmetric simulations for two reasons: (a) as will be shown later, the main process of the bubble
104 growth and collapse are characterised by axial symmetry and only at the last stages of the experiment,
105 after the rebound of bubbly structures, significant asymmetry develops (b) pursuing a full 3D
106 simulation would be very computationally expensive. A 2D rectangular domain of 89.1 x 190.2mm
107 was used, which corresponds to a cylinder of 178.2mm diameter. The influence of the boundaries is
108 expected to be weak, since the maximum bubble radius examined is ~5.2mm.

109 The computational domain is positioned in such a way that the point (0, 0) corresponds to the axis
110 of symmetry at the initial free surface level (see Figure 3). No-slip wall boundary conditions are
111 placed at the side and the bottom of the container and fixed pressure at the open top of the container.
112 In the experiments the container is connected to a vacuum pump that achieves the desired pressure
113 level.

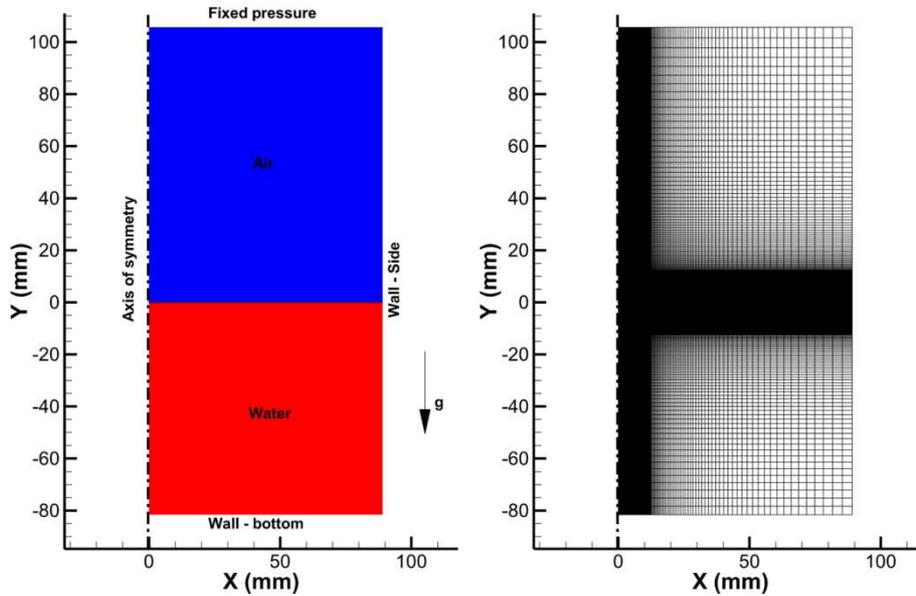

Figure 3. Configuration used for the simulation. Left: the 2D computational domain used. Right: the mapped computational mesh with refinement in the area of interest.

The 2D rectangular domain was meshed with a mapped-type structured mesh¹⁶, with local refinement in the area of interest, which spans in the x -direction from 0 to 12mm and in y -direction from -12 to 12mm. The aim of this refinement region is to capture with adequate resolution the bubble growth and collapse, without needing an excessive amount of computational elements in the whole container. The computational domain consists of 180000 cells and in the area of interest the cell size is $50\mu\text{m}$.

The container is initially filled with 84.5mm of water, as in the experiment. The ambient pressure the experiment was conducted is $p_{amb} \sim 10320\text{Pa}$. This pressure is imposed at the fixed pressure boundary and is initially set at the air region of the computational domain. The hydrostatic component of the air column is omitted since it is insignificant (at an estimated air density of 0.12kg/m^3 , the hydrostatic pressure of the air column is $\sim 0.12\text{Pa}$). On the other hand, the water part is initialized with the hydrostatic pressure, since its contribution is not insignificant. Indeed, the hydrostatic pressure difference from free surface to the bottom of the container is $\sim 800\text{Pa}$, or $\sim 7\%$ of the ambient pressure level. Earth gravity ($g=9.81\text{m/s}^2$) is applied as an external forcing term at the $-y$ direction.

The laser-generated bubble is introduced as a high pressure gas bubble, as in the relevant work of Ando et al.¹⁷, located at the same location as in the experiments, i.e. at a distance $s=2.95\text{mm}$ below the free surface. This is done by patching an amount of gas in a circular shape with centre coordinates $(0, -2.95\text{mm})$, initial radius R_0 and initial pressure p_0 , see Figure 5. Initial radius R_0 should be as close as possible to the initial bubble radius of the experiment. However this poses several challenges, since the initial bubble is ~ 100 times smaller than the maximum bubble size¹⁵, thus a very high grid resolution would be required to capture it. Additionally, the state of fluid inside this bubble probably departs from traditional fluid states, such as gas or liquid, due to the extreme initial conditions of the bubble. On the other hand, if one desires to patch a larger bubble, then it would be necessary to introduce the relevant velocity field generated by the bubble expansion. While this could be done in a perfectly spherical bubble in a spherically symmetric environment, it is not possible such a shortcut to be applied here, since there is a strong deviation from spherical symmetry due to the pressure gradient and the free surface. It becomes apparent that a compromise has to be made. A smaller bubble would be closer to reality, but it would require extreme resolution to capture, not to mention the questionable nature of the fluid inside it. On the other hand, a larger bubble would be easier to simulate but it will be difficult/impossible to initialize properly the consistent velocity field around it. For the given configuration it was found that an initial bubble size of 0.1mm was enough to describe properly the bubble growth, giving results in accordance to the experiment.

155
 156
 157

Figure 5. Initial conditions for the bubble interaction with the free surface. The frame at the bottom right is a zoomed in view at the initial bubble location.

158

The choice of the initial pressure and radius is also not trivial, since there is no simple methodology correlating the temporal evolution of the actual bubble size, given the initial pressure, due to the asymmetric expansion of the bubble. Still, a quick estimation can be made through the Rayleigh-Plesset equation in the sense that initial pressures that predict a spherical bubble radius less than the maximum found from the experiments can be safely discarded. The standard Rayleigh-Plesset equation¹ was used, in the form:

$$\rho \left[R\ddot{R} + \frac{3}{2}\dot{R}^2 \right] = p_v - p_\infty + p_{g0} \left(\frac{R_0}{R} \right)^{3n} - \frac{2\sigma}{R} - 4\mu \frac{\dot{R}}{R} \quad (1)$$

166
 167

where:
 ρ is the water liquid density, 998.2kg/m^3

- 168 - R is the bubble radius, $\dot{R} = dR/dt$ and $\ddot{R} = d^2R/dt^2$
- 169 - p_v is the vapour pressure.
- 170 - p_∞ is the pressure at the bubble level, including the hydrostatic pressure, i.e. $p_\infty = p_{amb} + \rho g s$, thus
- 171 $p_\infty = 10350\text{Pa}$.
- 172 - p_{g0} is the initial bubble pressure, tuned to predict a similar maximum bubble radius as the
- 173 experiment.
- 174 - σ is surface tension, equal to 0.072N/m . It has to be highlighted that surface tension, even if
- 175 included, has a nearly unnoticeable effect. Collapse time is affected less than 0.3% and maximum
- 176 radius less than 0.15% with the inclusion of surface tension.
- 177 - μ is the dynamic viscosity of water, i.e. $1.01 \cdot 10^{-3}\text{Pa}\cdot\text{s}$
- 178 - n is a polytropic exponent, depending on the thermodynamic process inside the bubble, e.g. for
- 179 adiabatic it is equal to the heat capacity ratio and for isothermal it is unity. In this study a value close
- 180 to unity has been used, since it matches better the experimental data.

181 In the present investigation, the vapour pressure is ignored. Whereas the vapour pressure is

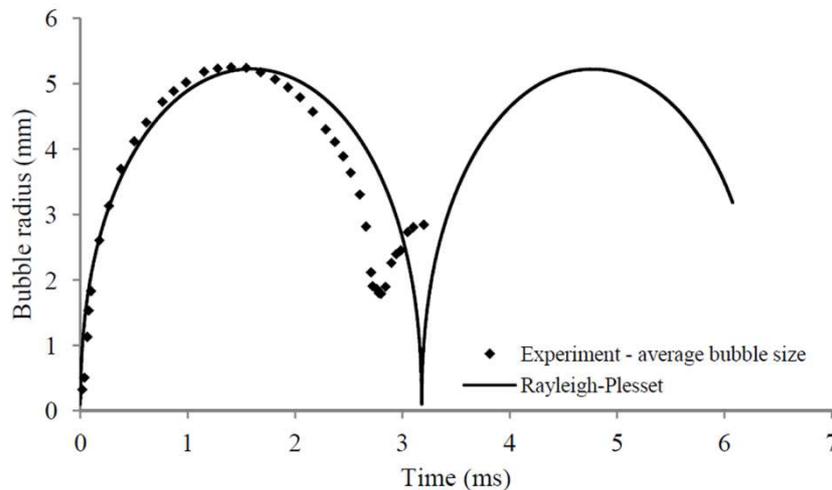

182 definitely not insignificant, the fast expansion and collapse of the bubble poses some questions on

183 whether the mass transfer through the bubble interface is fast enough so that the vapour pressure

184 inside the bubble is always equal to saturation pressure.

185 Assuming an initial pressure p_{g0} of 1000bar for an initial bubble $R_0=0.1\text{mm}$, one obtains the

186 following evolution of bubble size:

187 Figure 6. Time evolution of the experimental bubble size and comparison with the Rayleigh-Plesset solution for $R_0=0.1\text{mm}$

188 and $p_{g0}=1000\text{bar}$.

189

190 The deviation between the bubble development in the experiment and the solution of the Rayleigh-

191 Plesset equation should be expected, given the assumptions of spherical symmetry and infinite space

192 of the latter. In any case, considering the results in Figure 6, it becomes apparent that one needs at

193 least an initial pressure level of 1000bar in a bubble for an initial radius of 0.1mm, in order to be able

194 to reach a maximum radius of $\sim 5\text{mm}$. This greatly limits the number of trial-and-error runs that have

195 to be conducted to find the appropriate pressure level that gives the same maximum radius as in the

196 experiment.

197 B. Numerical model

198

199

200 The numerical model that was used for the CFD simulations is based on the Volume Of Fluid

201 (VOF) method, since it is of interest to maintain a sharp interface between the two involved phases,

202 with topological changes of the interface. As mentioned, only water and gas are considered, whereas
 203 vapour presence and mass transfer is ignored. The justification of this assumption is the fast process
 204 of bubble growth and collapse that means there is little time available for effective mass transfer.

205 Continuity and momentum equations are solved, while thermal effects are ignored. The equations
 206 solved, based on the viscous form of the Navier-Stokes equations, (for more information, the
 207 interested reader is addressed to standard CFD textbooks, such as ¹⁸⁻²¹), are as follows:

208 - Continuity equation:

$$209 \quad \frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{u}) = 0 \quad (2)$$

210 where \mathbf{u} denotes the velocity vector of the flow field.

211 - Momentum equation:

$$212 \quad \frac{\partial \rho \mathbf{u}}{\partial t} + \nabla \cdot (\rho \mathbf{u} \otimes \mathbf{u}) = -\nabla p + \nabla \cdot \boldsymbol{\tau} + \rho \mathbf{g} + \mathbf{f} \quad (3)$$

213 where ρ is the density of the fluid, p is the pressure, \mathbf{g} is the gravity vector, \mathbf{f} are body forces and $\boldsymbol{\tau}$ is
 214 the stress tensor, defined as follows:

$$215 \quad \boldsymbol{\tau} = \mu [\nabla \mathbf{u} + (\nabla \mathbf{u})^T] + \lambda (\nabla \cdot \mathbf{u}) \mathbf{I} \quad (4)$$

216 In eq. 4, \mathbf{I} is the identity matrix and μ is the dynamic viscosity of the fluid; for the pure phases it is
 217 set to 1mPa's and 17.1 μ Pa's for water and air accordingly. Term λ denotes the bulk viscosity of the
 218 fluid which acts only on passing waves; here it was set to $-2/3\mu$, which is an assumption commonly
 219 used, see ^{18, 19, 22}. Even if this value is mainly suggested for monoatomic gases ²³, the simulation
 220 results did not change significantly when using a value of 2.5mPa.s for water, as suggested by the
 221 work of Holmes et al. ²⁴; to be precise, there was an indiscernible difference in the values of the
 222 pressure field at the vicinity of the passing waves of $\sim 0.14\%$. Since the effect of bulk viscosity is only
 223 related to passing waves, it is unlikely to affect the general dynamics of the flow. Also, due to the
 224 minor influence it was found to play, and due to the uncertainties in its values (for example Holmes et
 225 al. ²⁴ measured the aforementioned value for sound waves of minimum frequency of 15MHz for water
 226 at 25°C, but it is known that there is a frequency dependence of λ ²³), it was decided to resort to the
 227 more standard and commonly used value of $-2/3\mu$, for which results will be presented hereafter. The
 228 Reynolds number of the flow ranges around 10000 or less, for the majority of the simulation time, so
 229 turbulence modelling has not been used.

230 Surface tension effects are included, employing the Continuum Surface Force Model which
 231 represents surface tension as a volume force in cells where there is an interface, i.e. volume fraction
 232 varies from zero to unity, see Brackbill²⁵. The value for surface tension coefficient used is
 233 $\sigma=0.072\text{N/m}$, as in the Rayleigh-Plesset equation in the previous section. In any case, surface tension
 234 effects are considered minor, given an indicative Weber number of ~ 1400 for the jet inside the bubble.

235 - Volume fraction equation ²⁶:

$$236 \quad \frac{\partial a \rho_G}{\partial t} + \nabla \cdot (a \rho_G \mathbf{u}) = 0 \quad (5)$$

237 where a represents the volume fraction and ρ_G the density of the gas phase. In the interface, where a
 238 varies from zero to unity, volume fraction averaging is performed for determining the value of
 239 viscosity and density.

240 Whereas in the actual experiment there is significant influence of heating effects, due to laser
 241 interaction with the liquid, the resulting fluid state is not possible to describe with traditional equation
 242 of states, such as ideal gas or other, since plasma generation and reactions take place. For this reason
 243 some simplifications had to be made and the energy equation has been omitted, since it is redundant
 244 in the thermodynamic closure chosen. Even with the omission of thermal effects, both phases are
 245 assumed compressible, obeying the following equations of state:

246 - for the liquid, the Tait equation of state:

$$247 \quad p = \frac{\rho_0 c_0^2}{n_l} \left(\left(\frac{\rho}{\rho_0} \right)^{n_l} - 1 \right) + p_0 \quad (6)$$

248 where, ρ_0 is liquid density, equal to 998.2kg/m³, c_0 the speed of sound, equal to 1450m/s, at the
249 reference state $p_0=3490$ Pa. The exponent n_l is set to 7.15, according to relevant literature on weakly
250 compressible liquids, such as water²⁷. Choice of the Tait equation of state is justified considering that
251 it matches closely the IAPWS liquid water data²⁸, comparing to simple linearized equations (as e.g. in
252 ²⁹), especially at extreme pressures, where the deviation in predicted densities may exceed 10%.

253 - for the gas, a polytropic equation of state is used:

$$254 \quad p = k\rho^n \quad (7)$$

255 Constant k is case dependent; here it is set assuming a gas density of ~ 0.12 kg/m³ (calculated from
256 ideal gas for a temperature of 25°C) at the ambient pressure of 10320Pa. The exponent n is set close to
257 unity, as in the Rayleigh-Plesset equation. The reason for resorting to this equation of state is twofold;
258 first of all it is practically the same equation of state in the Rayleigh-Plesset equation. Secondly, it is a
259 simple equation that can describe the compression and expansion of the bubble with the omission of
260 thermal effects. For both equations of state, speed of sound c is defined as follows³⁰:

$$261 \quad c = \sqrt{\left(\frac{dp}{d\rho} \right)} \quad (8)$$

262 Equations (2) and (3) are solved with a pressure-based algorithm, i.e. a pressure correction
263 equation is solved. Then the pressure correction is linked to a velocity correction and to a density
264 correction through the speed of sound (eq. 8, see also^{18,31}), to satisfy mass balance of fluxes in each
265 cell. In order to minimise the effect of numerical diffusion, which could affect the development of the
266 bubble during the whole process of growth and collapse, second order upwind schemes have been
267 used for the discretization of density and momentum, while the VOF phase field has been discretized
268 using a compressive differencing scheme³² to maintain a sharp interface. Briefly stated here, the
269 particular scheme is based on high resolution differencing scheme and the Normalised Variable
270 Diagram to achieve boundedness; the interested reader is addressed to O. Ubbink PhD thesis³³, Ch. 4,
271 for more information. Time stepping is done with an adaptive method, to achieve a Courant-
272 Friedrichs-Lewy (CFL) condition²⁶ for the free surface propagation of 0.2. This is necessary, to limit
273 as much as possible the interface diffusion and maintain solution accuracy at near the free surface³⁴.
274 The solver used is implicit pressure based and this removes any restrictions on the acoustic courant
275 number, which is ~ 10 (on average) considering the minimum cell size and the maximum wave
276 velocity.

277

278 IV. RESULTS

279

280 The first step in the solution process is to determine the initial pressure p_{g0} inside the bubble for the
281 chosen radius $R_0=0.1$ mm. As mentioned before, the solution of the Rayleigh-Plesset equation helps in
282 narrowing the possible pressure range, since a pressure level of at least 1000bar is required inside the
283 bubble. Starting from an initial pressure of e.g. 1500bar, a maximum bubble radius is predicted by the
284 Rayleigh Plesset equation. For the same conditions, the maximum bubble radius predicted by the
285 simulations was smaller; this is expected due to the asymmetric bubble expansion. The ratio between
286 the Navier Stokes and Rayleigh Plesset calculated radius was used to determine a correction factor.
287 Applying this correction factor to the Rayleigh Plesset equation enabled the calculation of a more
288 accurate prediction of the initial pressure that gives a maximum bubble radius of ~ 5.2 mm. Potentially
289 the aforementioned process should be repeated several times, until the desired maximum radius is

290 achieved. However, in practice, only one iteration was needed to determine the initial pressure that
291 gives a maximum bubble radius of $\sim 5.2\text{mm}$, which is 2180bar.

292 In the following figures, selected instances of the developed flow field are shown. Each image is
293 separated by the axis of symmetry (dashed-dotted line) in two parts. The left part shows the pressure
294 field and the right part the velocity field. The thick black line indicates the liquid/gas interface. White
295 regions in the pressure field indicate tension and can be correlated to secondary bubble formation
296 found in the experiments. Note that the pressure/velocity scales are not the same, since there is a
297 strong variation over time. Whenever possible, images from high speed movies of the experiment are
298 provided; it must be highlighted that camera angle and lighting were chosen as to depict in the best
299 possible way the bubble shape evolution and not the shape of the free surface, which cannot be
300 derived from the present images. Indicative instances of the free surface shape can be found in a
301 recent work of Supponen et al.¹⁴. Alternatively, a video showing both the bubble and part of the free
302 surface can be found in the Gallery of Fluid Motion by the same authors³⁵.

303 A very important observation is the fact that during the expansion of the bubble, a shock wave is
304 emitted. When this shock wave interacts with the free surface, part of it is transmitted in air as a weak
305 shock wave, whereas a significant part is reflected back in the liquid as a Prandtl-Meyer rarefaction
306 wave causing tension and resulting to the excitation of bubbles to expand. This effect is well known in
307 the literature, in interactions of shock waves and free surfaces, see e.g.^{17, 36-38}. The whole process of
308 shock wave interaction with the free surface is visible in Figure 7:

309 - At $2.8\mu\text{s}$ (Figure 7a) the shock wave expands in all directions, but reflects at the free surface,
310 forming a rarefaction wave and causing locally tension in the liquid between the bubble and the free
311 surface.

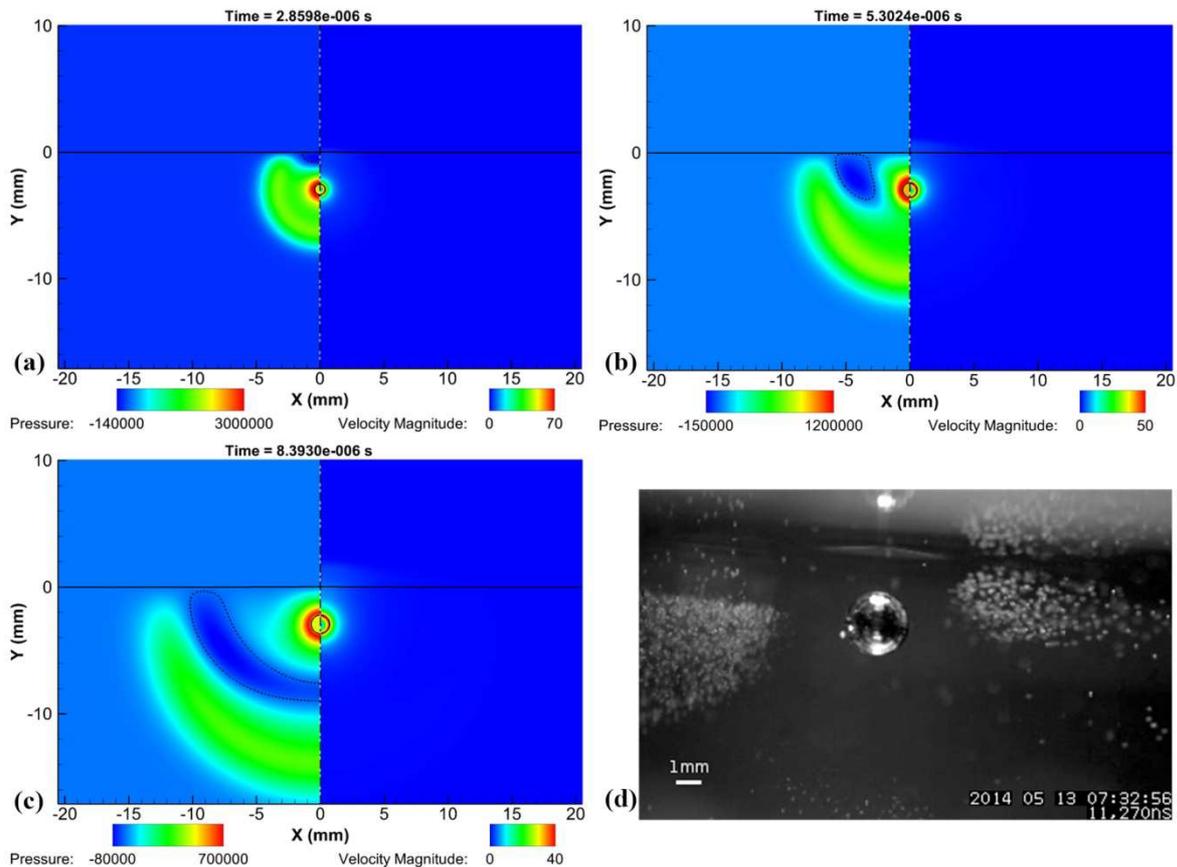

312 - At $5.3\mu\text{s}$ (Figure 7b) the tension wave moves and is located at the sides of the bubble, whereas
313 the shock wave further propagates.

314 - At $8.4\mu\text{s}$ (Figure 7c) the shock wave continues to expand closely followed by the tension wave. At a
315 similar time instant in the experiment (Figure 7d), secondary bubbles emerge at the sides and under
316 the bubble. During these early stages of bubble expansion the bubble shape remains close to spherical.

317 In all the aforementioned figures negative absolute pressures are shown in areas of tension. Such
318 pressures are naturally predicted by the Tait equation of state, since it represents the behaviour of a
319 weakly compressible elastic medium, such as liquid water. In reality, however, such magnitudes of
320 negative pressures may not appear, since secondary bubble generation, as shown in Figure 7d, will
321 relieve tension.

322 At later bubble growth stages, the bubble shape deviates from spherical and assumes an oval
323 shape, see Figure 8a or Figure 8c. This is a direct consequence of the lower inertia of the fluid towards
324 the free surface, causing a biased expansion towards the upwards direction. However, as the gas
325 inside the bubble expands pressure inside the bubble drops, eventually decelerating the expansion and
326 causing the collapse of the bubble. The maximum bubble radius predicted with CFD is $\sim 5.3\text{mm}$, close
327 to the one found from the experiment, which is 5.25mm , ensuring that the initial pressure estimation is
328 accurate enough, at least for the present study. During the collapse, a downwards moving jet is formed
329 (Figure 8e). The jet is predicted to have a radius of $\sim 0.5\text{mm}$, which is in agreement with the
330 experiment. However, contrary to the experiment the predicted jet velocity is somewhat higher: the
331 CFD results indicate a velocity of $\sim 14\text{m/s}$, whereas the jet velocity in the experiment is $\sim 9\text{m/s}$. This
332 discrepancy, which is also found in the slightly faster collapse of the CFD simulation in respect to the
333 experiment, was found to be unrelated to the mesh resolution (finer mesh yielded differences less than
334 1% in e.g. jet velocity). Additionally the bubble mass is conserved with a maximum error of 0.15%,
335 thus the mismatch is mainly attributed to the thermodynamic model of the gas inside the bubble,
336 rather than numerical inaccuracies. Still for the level of complexity involved the results can be

337 considered acceptable. Another potential source of the discrepancy is experimental error due to
 338 optical distortion of the jet from the bubble wall.
 339

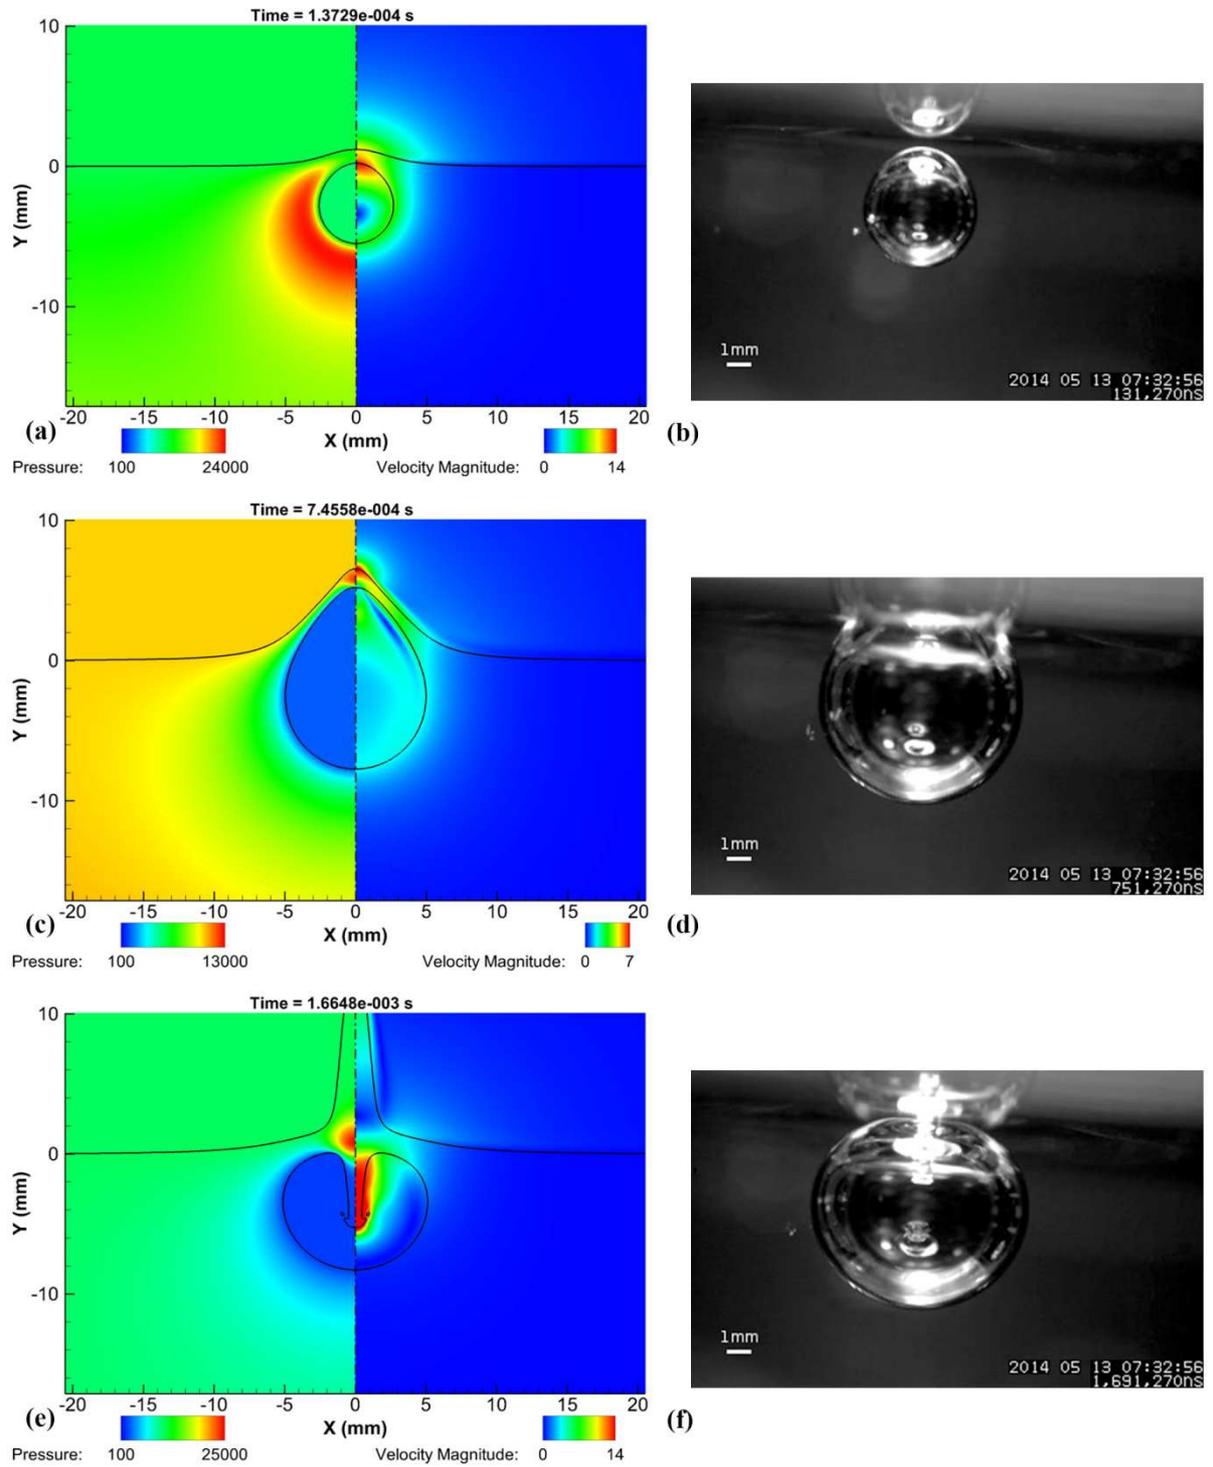

340
 341 Figure 7. Initial stages of bubble expansion. Note that the dashed line delimits the liquid under tension; this effect can be
 342 correlated to the formation of smaller bubbles near the main bubble.
 343

344 Another interesting effect that is found at the jet is the mushroom cap (see Figure 8e, f); this effect
 345 is the manifestation of well known interfacial instabilities, like the Rayleigh-Taylor or the Richtmyer–
 346 Meshkov instabilities³⁹. The radius of the jet cap is predicted to be ~1mm, in accordance with
 347 measurements from the experiment, see¹⁴.

348 After the jet impacts the bottom of the bubble, it deforms it in such a way that a gaseous pocket is
 349 formed, see Figure 9a, b. Later on the gaseous pocket detaches from the initial bubble. The initial
 350 bubble has a toroidal structure from now on (referenced as torus-1), since it has been pierced by the
 351 jet. The detached pocket has also a toroidal structure (Figure 9c, denoted as torus-2), as shown from
 352 the simulation. Evidence of the toroidal structure of the gas pocket is found from the photos of the
 353 experiment as well (Figure 9d), since the light reflections inside the gas bubble indicate an internal
 354 structure in the form of a vertical liquid core. Both toruses further collapse and expand again; torus - 1
 355 remains relatively intact, whereas torus - 2 splits further (Figure 9e, f). At later stages, torus-2
 356 collapses and then further splits, see Figure 10a, b. All toroidal bubbly structures start to expand and
 357 form an agglomeration, see Figure 10c, d.

358 The suspected mechanism of the splitting of torus-2 is shear layer instability, which potentially
 359 could be related to the Kelvin Helmholtz instability, since there is shear across a fluid interface. As
 360 shown in Figure 11 there is significant vorticity in the toroidal structures located at the lateral surface
 361 of the downwards moving liquid jet.

392
393

In Figure 12, the laplacian of the density field is shown, for selected instances of the simulation, to depict a numerical shadowgraph image ⁴⁰ from the simulation:

394
395
396
397

- At the instance of 35.4 μ s a strong shock wave is visible expanding in an arc-like shape in the water volume. Also a much weaker shock wave can be observed in the air volume, just above the epicentre of the bubble expansion. Both of these shock waves are formed due to the initial bubble expansion.

398
399
400

- At 137 μ s there is an interference pattern inside the liquid volume, due to reflection of pressure waves at the walls. The much weaker shock wave travelling in air, above the liquid, is still expanding and visible.

401

- Later on, at 1.865ms a shock wave is formed due to the impact of the jet on the bubble wall.

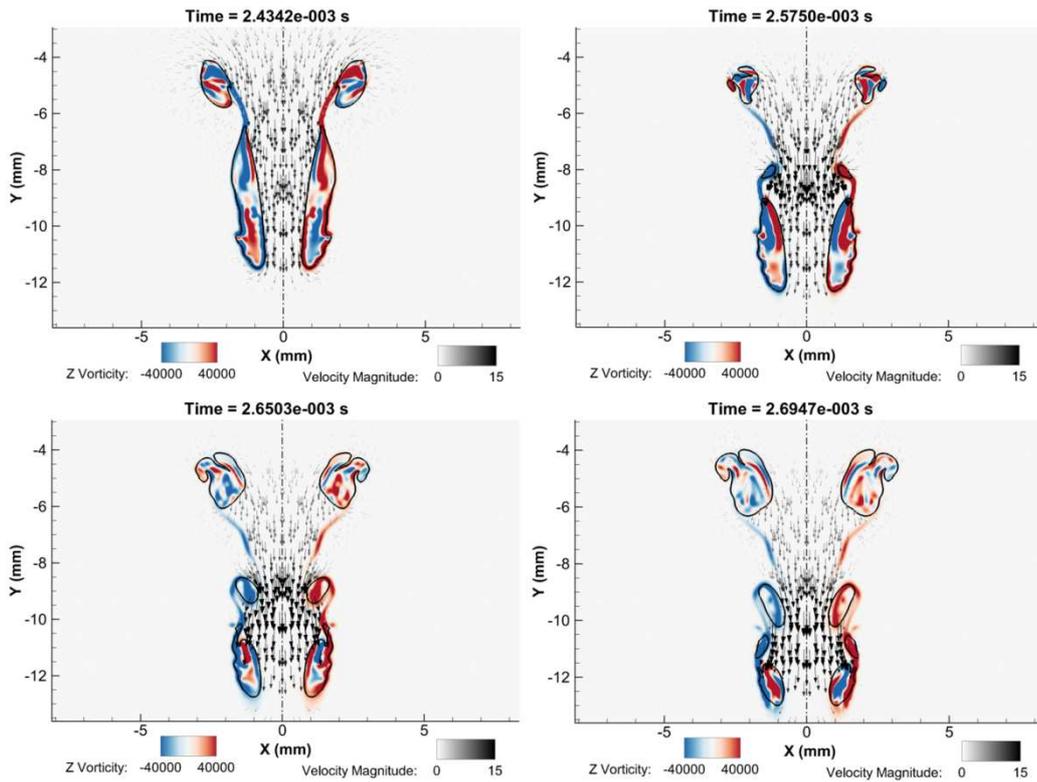

402

- At 2.53ms several shock waves are emitted, due to the collapse of torus-1.

403
404
405

In Figure 13(multimedia view) an animation of the bubble development is shown, as predicted by the simulation, for the better understanding of the bubble shape evolution and the relevant deformation of the free surface.

423 V. DISCUSSION

424

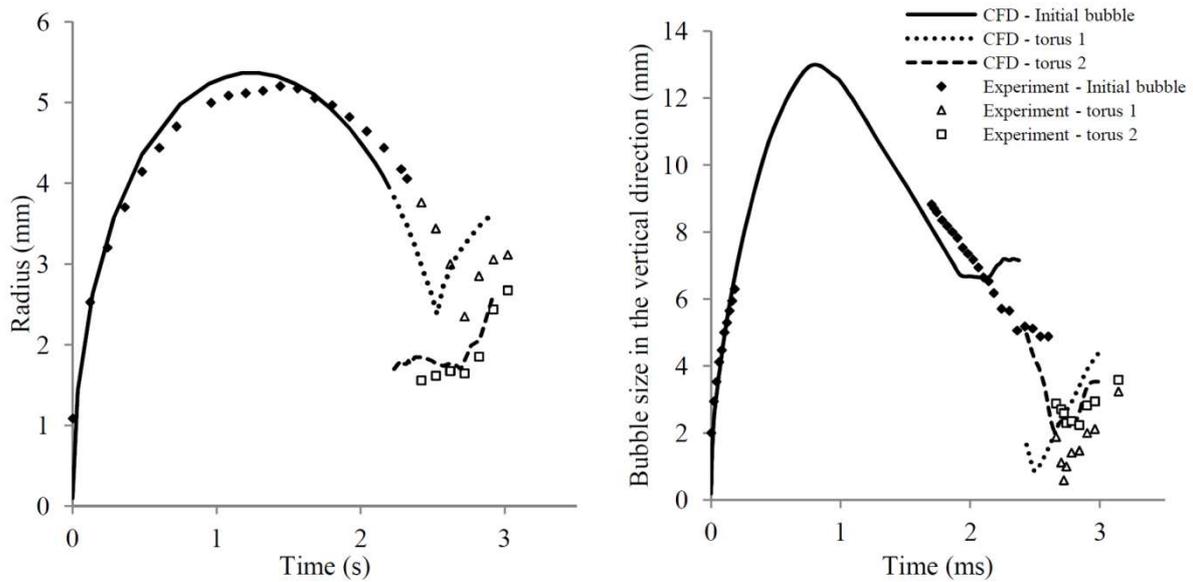

425 In Figure 14 the time evolution of the bubble radius and bubble height is presented, as found from
426 the experiment ¹⁴ and the CFD simulation. It is visible that the predicted collapse from CFD is
427 somewhat faster. Collapse of torus - 1 is found at 2.53ms, whereas in the experiment it occurs at
428 ~2.7ms, i.e. there is an error of ~6%. Still, the overall agreement of the bubble size evolution between
429 CFD and experiment is good, given the complexity of the problem and the simplicity of the
430 thermodynamic model of the gas involved, which is believed to be the main source of inaccuracy.
431 Unfortunately, due to the very complicated nature of the process inside the gas bubble, especially
432 during its generation, it was not possible at the current stage to employ a better model.

433 In any case, given the results of the study the following conclusions may be reached:

434 - In general, the whole process of bubble expansion and collapse is captured. Fine details such as
435 the formation of the tension waves, bubble shape and bubble breaking, jet size with mushroom-shaped
436 tip and finally the corona formation are captured.

437 - Even if surface tension has been included, its effect is nearly unnoticeable. This is justified by the
438 fact that the growth/collapse process at these bubble sizes is mainly inertial dominated: for example,
439 as mentioned above, bubble collapse time is affected less than 0.3% as found from the Rayleigh-
440 Plesset equation. The only exception of this is the formation of the corona, where local Weber number
441 is ~50.

442 - The thermodynamic model of the gas employed is simplistic, but can provide a simple
443 methodology for including the bubble gas effects without needing to resort to exotic equations of state
444 or other advanced techniques, with good accuracy in respect to reality.

446

447

448

Figure 14. Time evolution of the bubble size for the initial bubble and the two toruses formed after the jet impact. Comparison of the CFD and experimental results¹⁴.

449

450

451

In case a more accurate representation of the bubble gas is required, there are two main directions to be pursued:

452

453

454

455

456

457

1. One is to include the mass transfer from liquid water to vapour. In the Rayleigh-Plesset equation the mass transfer rate is assumed to be infinite, since vapour pressure inside the bubble is always equal to saturation pressure. In reality the mass transfer is finite, however the formulations used in the literature are based on the Hertz-Knudsen evaporation/condensation formula⁴¹, which depends on molecular characteristics, such as the accommodation coefficient⁴, see e.g. Lauer et al.¹¹ or Fuster et al.⁴².

458

459

460

461

462

463

464

465

466

2. Another improvement is to include the thermal effects during bubble expansion and collapse. This will require to simulate the early stages of expansion at rather extreme conditions, since initial conditions for the temperature/internal energy will be needed. For example, in the present study the maximum bubble volume is $\sim 600\text{mm}^3$ and this corresponds to an energy of $\sim 6.7\text{mJ}$. Given though that some energy is dissipated to the rest of the liquid due to heating losses, it is reasonable to assume that the initial bubble seed is heated by $\sim 12\text{mJ}$ of laser energy. Under the assumption that the initial bubble of $R_0=0.1\text{mm}$ is almost instantaneously heated by this energy, thus the density change is almost insignificant, then the enthalpy rise is equal to $\sim 3000\text{kJ/kg}$. Unfortunately existing water/vapour libraries are rather inaccurate or not applicable at such conditions:

467

468

469

470

471

472

473

474

475

476

477

- The IAPWS-IF97 formulation which is probably the most accurate for water/steam²⁸, is not applicable for pressures beyond 1000bar and for highly superheat steam beyond 500bar.

- NIST databases⁴³, while could be used at such conditions, are of questionable accuracy; for the conditions mentioned above, i.e. density $\sim 998.2\text{kg/m}^3$ and enthalpy $\sim 3000\text{kJ/kg}$ the predicted fluid pressure is 11000bar and temperature 850K; in the authors' opinion the temperature look rather low (there are research studies predicting temperatures of the order of 10000K, see⁴⁴), whereas pressure seems very high. Besides, the NIST database is a fitting of a Helmholtz energy or Benedict-Webb-Rubin equation of state to experimental data, thus accuracy at adverse conditions is not guaranteed. Needless to say that for 11000bar and 850K the ideal gas equation predicts a density of 2801.7kg/m^3 .

While all the above are a rather crude estimate of the conditions at the beginning of the bubble expansion, it becomes apparent that there is an important problem of a consistent thermodynamic

478 closure at the conditions involved. More research is required on the subject, that probably departs
479 from traditional fluid dynamics, computational or experimental, since the conditions may involve
480 other effects as dissociation, reactions and plasma.

481

482 VI. CONCLUSION

483

484 In this work, a description of the interaction of a laser-generated bubble with free surface is
485 provided, comparing the results of experiments and CFD simulations based on the VOF methodology.
486 Simulations were successful in the prediction of bubble expansion and collapse, both qualitatively and
487 quantitatively, whereas pressure wave propagation effects were identified. Fine details of the
488 liquid/gas interface were observed, such as the mushroom cap at the tip of the jet, or the splitting of
489 the torus-2 in an agglomeration of toroidal structures. While some deviations from the experimental
490 results exist, the overall qualitative and quantitative agreement is rather good, proving that CFD can
491 be an invaluable tool for shedding light to complicated bubble dynamics phenomena, in a non-
492 intrusive way. Potential improvements of the current study involve mainly the thermodynamics of the
493 gas inside the bubble.

495 ACKNOWLEDGMENTS

496

497 The research leading to these results has received funding from the People Programme (IAPP Marie
498 Curie Actions) of the European Union's Seventh Framework Programme FP7/2007-2013/ under REA
499 grant agreement n. 324313. The authors would like to acknowledge the contribution of The Lloyd's
500 Register Foundation. Lloyd's Register Foundation helps to protect life and property by supporting
501 engineering-related education, public engagement and the application of research. Also, the authors
502 would like to acknowledge the support of the Swiss National Science Foundation (Grant No. 513234)
503 and the European Space Agency.

504

505 Nomenclature

506

s	Bubble generation depth (m)
p_{amb}	Ambient pressure (Pa)
ρ	Density (kg/m^3)
R	Bubble radius (m)
R_0	Initial bubble radius (m)
\dot{R}	Bubble interface velocity (m/s)
\ddot{R}	Bubble interface acceleration (m/s^2)
p_v	Vapour pressure (Pa)
p_∞	Far-field pressure (Pa)
p_{g0}	Initial gas pressure (Pa)
σ	Surface tension (N/m)
μ	Dynamic viscosity (Pa.s)
\mathbf{u}	Velocity vector field (m/s)
$\boldsymbol{\tau}$	Stress tensor (Pa)
\mathbf{g}	Acceleration of gravity (m/s^2)
\mathbf{f}	Body/volume forces vector (N/m^3)
λ	Bulk viscosity coefficient (Pa.s)
a	Gas volume fraction
n	Polytropic exponent (for gas) (-)
n_l	Tait equation exponent (for liquid) (-)
ρ_0	Reference density (kg/m^3)

c_0	Reference speed of sound (m/s)
p_0	Reference pressure (Pa)
k	Constant of polytropic gas process $\left(\frac{Pa}{(kg/m^3)^n} \right)$
