Abstract

Background. Against the background of very limited evidence, the present study aimed to prospectively examine the impact of maternal postpartum PTSD symptoms on four important areas of child development, i.e. gross motor, fine motor, communication, and social-emotional development.

Methods. This study is part of the large, population based Akershus Birth Cohort. Data from the hospital's birth record as well as questionnaire data from 8 weeks and 2 years postpartum were used (n=1,472). The domains of child development that were significantly correlated with PTSD symptoms were entered into regression analyses. Interaction analyses were run to test whether the influence of postpartum PTSD symptoms on child development was moderated by child sex or infant temperament.

Results. Postpartum PTSD symptoms had a prospective relationship with poor child social-emotional development two years later. This relationship remained significant even when adjusting for confounders such as maternal depression and anxiety or infant temperament. Both child sex and infant temperament moderated the association between maternal PTSD symptoms and child social-emotional development, i.e. with increasing maternal PTSD symptom load, boys and children with a difficult temperament showed to have comparatively higher levels of social-emotional problems.

Conclusions. Examining four different domains of child development, we found a prospective impact of postpartum PTSD symptoms on children’s social-emotional development at two years of age. Our findings suggest that both boys and children with an early difficult temperament may be particularly susceptible to the adverse impact of postpartum PTSD symptoms. Additional studies are needed to further investigate the mechanisms at work.
Introduction

The importance of women’s health during pregnancy and after birth for fetal and infant development is well established. Women’s physical health in pregnancy is associated with the health of the infant and reduced risk of later adult-onset diseases such as metabolic syndrome and cardiovascular disease (Lau et al., 2011). Women’s mental health is also important. Stress and anxiety during pregnancy are associated with preterm labour, poor infant outcomes, and greater cognitive, behavioural and interpersonal problems in young children (Glasheen et al., 2010). Similarly, depression in pregnancy and after birth can have an adverse impact on women, their children, and their relationships (WHO, 2016). This has led to an international call for the integration of maternal mental health into maternal and child health programmes (Rahman et al., 2013).

Research examining the impact of postpartum mental health on child development has predominantly focused on depression (Rahman et al., 2013) and shows that postpartum depression is associated with reduced maternal sensitivity to their infant, poorer infant attachment and developmental outcomes, particularly for boys (Ramchandani et al., 2005, Sharp et al., 1995). However, it is clear that women can suffer from a range of mental illnesses, including post-traumatic stress disorder (PTSD) following a traumatic birth. Meta-analyses show PTSD after birth affects 3.1% of all postpartum women and 15.7% of women in high-risk groups such as those with severe complications in pregnancy (Grekin and O’Hara, 2014). This means that in the European Union and the USA approximately 153,000 and 118,000 women, respectively, may be affected every year (Eurostat Statistics Explained., 2015, Martin, 2015). Symptoms of PTSD include re-experiencing, avoidance and emotional numbing, hyperarousal, and negative cognitions and mood (American Psychiatric Association, 2013).

The impact of traumatic birth and postpartum PTSD symptoms on infants’ development is unclear because research in this area is scarce (McKenzie-Mcharg et al., 2015). However, there are a number of ways in which PTSD might affect the mother-baby relationship and have a negative impact on infant development. For example, if women associate their baby with the traumatic events during
birth then this might lead to women avoiding contact with the infant. Moreover, symptoms of emotional numbing may result in women being emotionally unavailable to their infants, which could influence the type of attachment the infant develops to the mother. Conversely, symptoms of hyperarousal and intrusion might lead to angry or intrusive parenting. PTSD is also highly comorbid with depression (Ayers et al., 2016), which has been shown to affect maternal sensitivity and be associated with poorer development in children.

There is some evidence to support the impact of PTSD on parenting. A series of case studies published by Ballard and colleagues (1995) illustrates one mother avoiding all contact with her baby and another becoming aggressive towards her older child (Ballard et al., 1995). Similarly, Moleman et al. (1992) presented the cases of three women with postpartum PTSD (i.e. 'partus stress reaction'), who all failed to meaningfully attach to their children. Further, qualitative studies show some women suffering from PTSD symptoms to report difficulties bonding with their infant and/or breastfeeding (Beck and Watson, 2008, Elmir et al., 2010, Fenech and Thomson, 2014), both of which may have long-term health implications for infants (Horta, 2007, Ip et al., 2007). However, evidence from quantitative studies is mixed and available studies have been based on small or self-selected samples. For example, an online survey of 152 parents (126 women and 26 men) found that symptoms of PTSD and depression were associated with a poorer parent-baby bond (Parfitt and Ayers, 2009). However, another study of 64 couples recruited from birth registers at a UK hospital found no association between PTSD symptoms and the mother-baby bond, although there were small correlations between PTSD symptoms and an unfavorable father-baby bond (Ayers et al., 2007).

Thus there are plausible reasons why PTSD might affect the mother-baby relationship and infant development, although evidence is limited in terms of scope and methodological rigor. The long-term impact of PTSD on the infant’s development is an area where very little research is available. To date, only one longitudinal study of 42 couples has been published that examined infant development in relation to parents’ mental health, including postpartum PTSD. This study found...
maternal postpartum PTSD to be associated with poorer cognitive development in infants at 17 months of age, as measured by the Bayley Scales (Parfitt et al., 2014). In contrast, less optimal language development was associated with maternal depression in pregnancy. This study also found that parents’ ratings of their infant’s temperament three months after birth were strongly associated with all child development outcomes. The strengths of this study include using a variety of measures to assess parents’ mental health and assessing child development by means of observational data. However, the study is limited in terms of sample size and representativeness. It is therefore difficult to know whether the results are generalizable. Moreover, little is known about whether subgroups of children are particularly vulnerable to develop problems when their mothers have suffered from postpartum PTSD. Results from the study mentioned above (Parfitt et al., 2014) indicate that children with difficult temperament might be especially at risk. In addition, according to the literature from postpartum depression (Ramchandani et al., 2005, Sharp et al., 1995), also male sex might represent a potential moderator.

To summarize, it is likely that maternal postpartum PTSD - an important women’s health issue - will have an adverse impact on child development. However, conclusions about such impact remain tentative because of the limited evidence available. McKenzie-McHarg and colleagues (2015) therefore have called for prospective studies with large, representative samples to establish the extent and nature of the impact of PTSD following childbirth on infant. The present study aimed to address this by examining the impact of maternal postpartum PTSD on four important areas of child development (i.e. gross motor, fine motor, communication, and social-emotional development) in a large, population based cohort study of women up to two years postpartum. Moreover, we investigate the role of potential confounding factors such as maternal depression and preterm birth and examine whether the association between postpartum PTSD and child development varies according to potential moderators such as the infant’s sex and temperament.

Methods
**Design and study population**

The Akershus Birth Cohort (ABC) study is a prospective cohort study which targeted all women scheduled to give birth at Akershus University Hospital, Norway, which serves approximately 350,000 people from both urban and rural areas. Recruitment took place from November 2008 to April 2010. Women were recruited for the study during their routine fetal ultrasound examination, which is performed at 17 weeks gestation, and were asked to complete questionnaires at 17 weeks gestation, 32 weeks gestation, 8 weeks postpartum and 2 years postpartum. Of the eligible women, 80% (n=3,752) agreed to participate and returned the first questionnaire. The number of eligible women dropped somewhat during the study time because some women had moved or were withdrawn from the study due to severe birth complications. Response rates were 81% (2,936 out of 3,621), 79% (2,217 out of 2,806) and 73% (1,480 out of 2,019) respectively. Detailed information regarding participation and drop out in the longitudinal design is provided in a study flow chart (see Supplementary material 1).

For the present study, we used questionnaire data from 8 weeks and 2 years postpartum as well as data obtained from the hospital’s birth record. Data for the birth record were electronically recorded by the hospital’s staff, including socio-demographic and medical information about the mother, the delivery, and the child. Birth record data were not registered for 8 participating women; thus, 1,472 women were included in the analyses. As less than 50% of the original participants were included in the current sample, we performed attrition analyses. More specifically, we included relevant socio-demographic and mental health variables (i.e. maternal age, education and symptoms of depression, anxiety and general PTSD symptoms) assessed at 17 weeks of gestation and the hospital’s birth record simultaneously as predictors of drop-out within 2 years postpartum in multiple logistic regression analyses. The results showed that women with higher education (OR .57, 95% CI .50-.65, p < .001), and older age (OR .97, 95% CI .96-.99, p < .001) were less likely to drop out of the study, whereas women with symptoms of depression (OR 1.05, 95% CI 1.02-1.07, p < .001) were somewhat more likely to drop out. Symptoms of anxiety and PTSD were not significantly related to
drop-out \((p > .05)\). Further information regarding the characteristics of the cohort as a whole \((n=3,752)\) compared to the final sample \((n=1,472)\) can be found in Supplementary material 2.

The ABC study obtained ethical approval from the Regional Committees for Medical and Health Research Ethics (approval number S-08013a), and all participants provided written informed consent.

**Measurement**

*Child development*

At two years of age, four domains of child development were assessed by means of the Ages & Stages Questionnaire (ASQ-3) and the Ages & Stages Questionnaire – Social-Emotional (ASQ:SE). Using the ASQ-3, mothers reported on their children’s gross motor (focuses on arm, body, and leg movements), fine motor (pertains to hand and finger movements) and communication development (covers babbling, vocalizing, listening, and understanding) (Squires et al., 2009). The scale consists of six items per domain, and items were coded “10” (yes), “5” (sometimes), or “0” (not yet); depending on whether or not a child is able to perform a certain task. Hence, scores may range from 0 to 60 in each domain. Internal consistency was \(\alpha = .79\) for communication development, \(\alpha = .59\) and \(\alpha = .44\) for gross and fine motor development, respectively.

In addition, using the ASQ:SE, mothers reported on their children’s social-emotional competence (e.g. self-regulation, compliance, interaction with people). The ASQ:SE questions are rated on a three-point scale indicating if the child performs a behavior ‘most of the time’ (0), ‘sometimes’ (5), or ‘never or rarely’ (10) (Squires et al., 2005). An additional check box allows for stating if a behavior is of concern to the parents; checked concerns score 5 additional points. Scores for each domain are totaled into an overall score: high total scores indicate possible developmental problems, while low scores suggest competent social-emotional behavior. With 26 questions to be answered, scores range from 0 – 390. The ASQ:SE scoring pattern is the opposite of the ASQ-3 on which low scores indicate the absence of skills. Reliability was \(\alpha = .51\).
PTSD symptoms following childbirth

The Impact of Event Scale (Horowitz et al., 1979) was used to measure PTSD symptoms at 8 weeks postpartum. The instrument is a self-rating scale that measures symptoms of intrusion (7 items) and avoidance (8 items). The scale has four response categories with the following weightings: 0 = not at all, 1 = rarely, 3 = sometimes, and 5 = often. Sum scores of the overall scale were computed (range 0-75), where higher scores reflect a higher degree of post-traumatic stress. The Impact of Event Scale has been validated in postpartum women (Olde et al., 2006) and can be used as a continuous or categorical measure, with scores over 19 reflecting clinically significant distress, and scores over 34 indicating that PTSD is likely to be present (Neal et al., 1994). Reliability in the present study was $\alpha = .85$.

Maternal mental health and demographic factors

Symptoms of depression during the past week were measured using the Edinburgh Postnatal Depression Scale (Cox et al., 1987) at 8 weeks postpartum. The Edinburgh Postnatal Depression Scale is a 10-item self-rating scale designed to identify postnatal depression. The scale has four response categories ranging from 0 to 3; thus, the total scores can range from 0 to 30. Higher scores reflect higher levels of depression, and reliability was $\alpha = .85$.

Also at 8 weeks postpartum, the 10 item anxiety scale of the Hopkins Symptom Check List was used to evaluate anxiety symptoms during the previous week. This scale has not been specifically validated for use in the perinatal population. However, a Norwegian study of n=1794 mothers, that used the Hopkins Symptom Check List, yielded comparable results for both postpartum and non-postpartum mothers (Eberhard-Gran et al., 2003). The scale has four response categories ranging from 1 to 4. Consequently, total scores range from 10 to 40, with higher scores indicating higher levels of anxiety (Nettelbladt et al., 1993). Reliability was $\alpha = .78$. 
Age at delivery and maternal education were obtained from the hospital’s birth records. Educational level was coded as “1” (more than 12 years of education; i.e., higher education) and “0” (12 or fewer years of education; i.e., primary and secondary education).

**Child factors**

Information regarding child sex was retrieved from the hospital’s birth record. Moreover, using the birth records, the birth was categorized as either term or preterm birth (born more than 3 weeks before the expected birth date; Tucker and McGuire, 2004). If this information was unavailable, gestational age was computed based on the first day of the woman’s last menstruation.

At 8 weeks postpartum, infant temperament was measured with a 10-item adapted version of the “Fussy/Difficult” Subscale of the Infant Characteristics Questionnaire (Bates *et al.*, 1979). This scale assesses infant difficultness as perceived by the primary caregiver. Mothers rated their infants’ usual mood and temperament on a 7-point rating scale, with higher scores reflecting greater infant difficultness. Reliability was $\alpha = .83$.

Current child health problems were assessed at child age 2 years and based on maternal report. Each health problem was treated as a dichotomous variable depending on whether or not it was present. Potential child health problems were: (1) impaired hearing; (2) impaired vision; (3) eczema; (4) asthma; (5) respiratory syncytial virus; (6) bronchiolitis; (7) urinary tract infection; (8) recurring ear infection; (9) food allergy/intolerance; (10) insufficient weight gain; (11) excessive weight gain; (12) nutritional deficiencies; (13) diabetes; (14) injuries or accidents; (15) others. Child health problems were then coded as “0” (no health problem) “1” (one health problem) or “2” (two or more health problems).

**Statistical analysis**

PTSD symptoms following childbirth were correlated with all four domains of child development at two years postpartum. Domains that were significantly correlated with PTSD symptoms were entered
into linear regression analyses. In the multiple regression analyses, we adjusted for potential confounders, i.e. maternal mental health and demographic factors as well as relevant child factors. In order to examine whether the influence of maternal mental health on child development was moderated by child sex, we conducted interaction analyses where maternal mental health, the child’s sex and the interaction term of these variables were included simultaneously in linear regression analyses predicting child development. Moreover, interactions between maternal mental health and child difficult temperament were tested in the same manner. Interaction terms that were significantly associated with child development were also entered in the multiple regression analyses including all potential confounders. As standard statistical techniques assume normal sampling distributions, we used bootstrapping to estimate standard errors in all analyses, as such standard errors are robust to deviations from normality (Efron and Tibshirani, 1993). More specifically, bias corrected and accelerated bootstrap standard errors, based on 5,000 bootstrap samples, were estimated. Missing values on the psychometric scales were substituted with the mean of each case if the number of missing items was ≤ 20%; otherwise, they were excluded from the analyses. Among the 1,472 participating women, the proportion of missing data for the variables included in the study varied from 0.3% for social-emotional development, infant temperament as well as PTSD, depression, and anxiety symptoms to 1.2% for fine motor development. The statistical package IBM SPSS 23 was used for all analyses.

Results

Demographic and clinical characteristics of the sample

The children’s mean birth weight was 3,545 grams (SD = 533 grams), and there were fewer girls (48%) than boys. The mean gestation period was 39.9 weeks, and 6% of the children were born premature. Mean maternal age at birth was 31.7 (SD = 4.5). The vast majority (98%) was either married or living with a partner, and a majority of the sample (73%) had an educational level beyond high school. 52% of the mothers reported that this was their first pregnancy.
Table 1 shows the distribution of the ASQ-3 and ASQ:SE scores. Boys had more developmental problems than girls in all domains of child development, particularly in the domain of communication.

**PTSD symptoms and child development**

At 8 weeks postpartum, 6.6% of women had clinically significant distress (scores above 19 on the Impact of Event Scale) and 1.9% had probable PTSD (scores above 34). The average score for PTSD symptoms following childbirth was 7.02 (SD=8.38). Mean scores for the subscales intrusion and avoidance were 4.40 (SD=4.97) and 2.54 (SD=4.11), respectively.

Table 2 shows correlations between PTSD symptoms, child development and all other variables included in the study. It can be seen that PTSD symptoms were significantly related to problems in the children's social-emotional development (r=.17). PTSD symptoms were not associated with the other developmental domains, i.e. gross motor, fine motor and communication development. Similar correlational patterns were found when examining intrusion and avoidance symptoms separately, although there was a small significant association (r=-.06) between intrusion symptoms and fine motor development, indicating that intrusion symptoms were related to less favorable development in this area.

Symptoms of depression and anxiety were strongly associated with each other (r=.68), and both were also clearly associated with PTSD symptoms following childbirth (r=.37 and r=.36 respectively). Moreover, symptoms of depression and anxiety were significantly related to the children’s social-emotional development (r=.23 and r=.19 respectively). Similarly, as with PTSD intrusion symptoms, there was a small significant association (r=-.08) between depressive symptoms and fine motor development (Table 2).

All measures of maternal mental health, i.e. symptoms of postpartum PTSD, depression and anxiety, were associated with maternal ratings of the infant having a difficult temperament 8 weeks
postpartum, though we found the largest association with symptoms of depression ($r=.31$) (see Table 2).

A multivariate regression model of PTSD symptoms and social-emotional development, adjusted for maternal mental health and relevant child factors, is shown in Table 3. It can be seen that the prospective effect of PTSD symptoms on social-emotional development at 2 years of age remained statistically significant ($\beta=.08$) after adjustment for confounders. Social-emotional development was also significantly associated with symptoms of depression, ratings of a difficult infant temperament 8 weeks postpartum, being born prematurely, and current child health problems (see Table 3).

We also conducted a multivariate regression analysis with PTSD intrusion symptoms as predictor and fine motor development as outcome, as they were significantly correlated in the bivariate analyses (see Table 2). However, after adjusting for confounders, this association was not significant anymore ($\beta=-.02$, $p > .05$).

Finally, we examined whether sex of the child moderated the association between maternal PTSD symptoms and child social-emotional development. Analyses showed a significant interaction effect ($\beta=.26$, $p < .01$) and a graphical representation of the interaction is depicted in Figure 1. The figure shows that girls and boys of mothers with no postpartum PTSD symptoms had similar levels of social-emotional development. However, with increasing maternal PTSD symptom load, boys showed to have increasingly higher levels of social-emotional problems, whereas girls’ levels of social-emotional problems increased at a slower rate with an increasing number of PTSD symptoms. Similar results were obtained when examining interaction effects with difficult temperament. Also here, a significant interaction effect emerged ($\beta=.23$, $p < .01$), indicating that the association between postpartum PTSD symptoms and problems in child social-emotional development was stronger among children with a difficult temperament, compared to children with a less difficult temperament. Both interaction effects remained statistically significant when entered in the multiple regression analyses including all confounders ($\beta=.25$, $p < .01$ for child sex and $\beta=.21$, $p < .05$ for
difficult temperament). No interactions were found for symptoms of depression or anxiety with child sex or difficult infant temperament.

Discussion

Summary and interpretation of results

Postpartum mental health is a central women’s health issue - not only for the mother but also for the well-being and the development of her child. Previous research on the impact of postpartum mental health has mainly focused on the role of postpartum depression. With regard to postpartum PTSD, however, research on childhood outcomes has been lacking. Given this context, the present study fills an important gap. The results showed that postpartum PTSD symptoms had a small predictive relationship with poor child social-emotional development two years later. This relationship remained significant even when adjusting for confounders such as maternal depression and anxiety and infant temperament. As we have accounted for above, postpartum PTSD symptoms may impact in a variety of ways. Symptoms of intrusion might lead to irritable or intrusive parenting, whereas avoidance symptoms might lead to women avoiding contact with their children, and emotional numbing might lead to mothers being emotionally unavailable. Differentiating PTSD symptoms into intrusion and avoidance symptoms, there was no considerable difference as of effect size in our sample. This suggests symptoms of intrusions and avoidance do not differ in the extent of the impact on the child’s social-emotional development. Other measured domains of child development showed no significant relationship with postpartum PTSD symptoms. We only found a small significant effect between intrusion symptoms and fine motor development but this effect disappeared once confounding factors were controlled for.

Infant difficult temperament was also related to all three measures of maternal mental health. These results are consistent with the study by Parfitt and colleagues (2014) who found that infant difficult temperament had small to medium associations with maternal depression, anxiety and PTSD (Parfitt et al., 2014). However, it is difficult to determine the direction of causality between
ratings of infant difficult temperament and maternal mental health. On the one hand, women’s ratings of their infant’s temperament may be affected by her mental health problems. On the other hand, a difficult infant might put more strain on women and increase their mental health problems.

In this study, early infant temperament also played a pivotal role in the development of social-emotional development problems. We found both a direct effect from infant difficultness to social-emotional development problems two years later, as well as a moderating effect. Maternal PTSD symptoms had a greater adverse effect on child social-emotional development, if the mothers rated their infants as having a difficult temperament eight weeks postpartum. This finding is consistent with Parfitt et al. (2014) who found that the largest prediction for infant developmental outcomes was afforded by parental perceptions of their infant’s characteristics.

In addition, we found an interesting interaction effect with child sex, namely that for boys, maternal PTSD symptoms eight weeks postpartum had a greater negative effect on social-emotional development at two years of age, compared to girls. The finding that boys are more vulnerable to poor developmental outcomes has been shown to be the case for postpartum depression as well (Ramchandani et al., 2005, Sharp et al., 1995), but to our knowledge this is the first time that is has been examined in relation to PTSD symptoms. Because boys are generally developmentally delayed compared to girls, they need to a greater degree help from a sensitive caregiver to regulate their emotions (Sharp et al., 1995). As a result, they might be specifically vulnerable to adverse parental influences (Ramchandani et al., 2005).

**Strengths and limitations**

To our knowledge, this is the first large scale, population-based study to investigate the longitudinal impact of postpartum PTSD symptoms on child development. Moreover, the inclusion of relevant confounders and the use of adequate statistical techniques, such as bootstrapping, to handle non-normal sampling distributions are strengths of the study. Still, some potential limitations are worth discussing. The fact that only Norwegian-speaking women were included resulted in a relatively
homogeneous, mainly Caucasian sample. Furthermore, as we have shown previously, there is reason to believe that there is a slight social gradient associated with participation in the study (Garthus-Niegel et al., 2014a, Garthus-Niegel et al., 2014b). Likewise, the somewhat selective attrition during the longitudinal course of the study, as demonstrated by attrition analyses, is an additional threat to the representativeness of the sample. However, it is important to bear in mind that selection bias does not necessarily influence the results when associations between variables are investigated (Nilsen et al., 2009).

Although we found significant associations between postpartum PTSD symptoms and social-emotional development at child age 2 years, the effects were only modest, as reflected in the relatively small size of the standardized regression coefficient. Consequently, caution is needed when recommending intervention. Still, we regard our results as clinically significant since we could show that postpartum PTSD symptoms was prospectively associated with poor social-emotional development over a long period of time. Also, effect sizes were not much larger for depression, for which there is an extensive literature underlining the importance for child development (Stein et al., 2014).

Even though we used one of few recommended universal screening tools qualified to investigate children’s development in infancy (Squires et al., 2009, Squires et al., 2005), internal consistency was somewhat low when assessing communication, fine motor, and social-emotional development. However, these three measures cover broad domains of development, and items assessing such constructs tend to correlate less highly than item collections reflecting a narrow, more tightly defined construct, in turn leading to lower reliability estimates. Further, as all data were based on mothers' reports only, parts of the relationship between maternal PTSD symptoms and child development may be due to a common method bias. For instance, mothers with mental health problems may be more inclined to report PTSD symptoms as well as developmental child problems. However, that the association between PTSD symptoms and child development holds when controlling for symptoms of depression and anxiety, makes this explanation less likely. Still, in
addition to mothers’ reports, future studies should assess child development with independent observers and via standardized observation procedures (e.g., using the Bayley Scales of Infant and Toddler Development; Bayley, 2006). Further, since the quality of mother-child bonding may be also relevant for child development, it would be of interest to assess this factor as well (e.g., using the standardized Strange Situation Procedure; Ainsworth et al., 2015).

**Conclusions**

Postpartum PTSD is highly likely to impact on women and their infants (Nicholls and Ayers, 2007) through a variety of mechanisms. Examining four different domains of child development we found a prospective impact of postpartum PTSD symptoms on children’s social-emotional development at two years of age. The size of the association was comparable to that of postpartum depression with children’s social-emotional development. In clinical practice the focus of postnatal care therefore ought to expand beyond depression and include postpartum PTSD as well. Further, our findings suggest that both boys and children with an early difficult temperament (as rated by their mother) may be particularly vulnerable to experience social-emotional development problems when their mothers suffer from postpartum PTSD symptoms. However, as this is the first large scale study that studied the prospective impact of postpartum PTSD symptoms on childhood development, additional studies are needed to replicate these findings and to further investigate the mechanisms at work.
