Surplus Analysis for Variable Annuities with a GMDB option

Haberman S.†, Piscopo G.††

Abstract
In this paper, we analyze the insurance surplus for a Variable Annuity contract with a Guaranteed Minimum Death Benefit (GMDB) option. Initially, we derive the first two moments of the distribution of the surplus; and subsequently, we develop the whole distribution using a stochastic model which involves an integrated analysis of financial and mortality risk for a portfolio of annuities with GMDB embedded options. We offer a model according which the premium can be modified as per the forecasts of mortality probabilities, interest rate and fund evolution. Moreover, the study enables us to determine the premium that leads to a required probability of insolvency, and so it can be used for an evaluation of the adequacy of solvency. Numerical examples illustrate the results.

**JEL classification:** G22

**Keywords:** Guaranteed Minimum Death Benefit option, financial risk, mortality risk, surplus, Variable Annuity.

1. Introduction
The Variable Annuity market has increased considerably in the past decade, when bullish financial markets and low interest rates have tempted investors to look for higher returns. Variable Annuities are very attractive to consumers, because they provide participation in the stock market. They are unit-linked annuity contracts, usually with a single premium payment up-front which is invested in one of several funds and they normally are designed with some embedded guarantees. “As VAs are essentially a new product class in the U.K., an industry standard definition does not yet exists...they are similar to unit linked retirement saving vehicle such as unit linked annuities... however the availability of guarantees distinguish them” (Ledlie et al. 2008). One of these features is the Guaranteed Minimum Death Benefit, an increasing-strike put option with a stochastic maturity date. In the basic form of product, when the insured dies, the beneficiary obtains a death benefit, which is equal to the maximum of the invested premium and the account value linked to the

fund. This guarantee is paid for by the VA holder in the form of a perpetual fee that is deducted from the account value linked to the underlying asset.

The purpose of this paper is to study the insurance surplus over time for a portfolio of Variable Annuities with GMDB options. There are 2 theoretical foundations for this work: on the one hand, we take into account the actuarial literature concerning the valuation of the Variable Annuity and GMDB option (Bauer, Kling and Russ (2006); Coleman, Yuying and Patron (2006); Milevsky M. and Posner (2001), Milevsky M. and Salisbury(2002), Milevsky M.A. and Promislow (2001)); on the other hand, we look at the actuarial research literature on insurance surplus and insolvency probability (Coppola et al. (2003), Dahl (2004), Hoedemakers et al. (2005), Lysenko and Parker (2007), Marceau and Gaillardetz (1999) Parker (1996) and Parker (1994)). The abovementioned papers deal with the stochastically discounted value of future cash flows in respect of life insurance and life annuity contracts. The innovative contribution of our work is to apply this methodology to a new product like a Variable Annuity with a GMDB option, extending the models appearing in the literature in order to study a product with a payments linked to a fund account. In the manner of Lysenko and Parker (2007), we adopt a definition of surplus as the difference between the retrospective gain and prospective loss: if we fix a valuation date $r$, the accumulated value to time $r$ of the insurance cash flows that occurred between times 0 and $r$ represents the retrospective gain and the present value at time $r$ of the cash flows that occur after $r$ is the prospective loss. We modify the model proposed by Lysenko and Parker (2007) in order to capture the uncertainty of a death benefit linked to a fund account. Further, we do not approximate the true probability function of surplus by its limiting distribution as in Lysenko and Parker, which takes into account the investment risk but treats the cash flows as given and equal to their expected value. Instead, in order to explore the longevity risk, we simulate the impact of both the financial and mortality factors on the retrospective gains and prospective losses. We adopt the same financial assumptions as in the Black and Scholes framework. The mortality hypothesis is based on the stochastic model suggested by Cox and Lin (2005) and developed by Ballotta, Esposito and Haberman (2006).

The paper is organized as follows: in section 2 we describe the model; in section 3 we define the surplus as the difference between the retrospective gain and prospective loss and derive the first two moments of its distribution; in section 4 we develop the financial model. Numerical results are shown in section 5 under a deterministic approach. In section 6, we develop the simulations and construct the surplus distribution following a stochastic approach and, in particular, we identify three components, relating respectively to interest, fund and mortality risks. Concluding remarks are offered in section 7.

### 2. The model

In this work, we consider a portfolio of identical Variable Annuities with a GMDB option, which are issued to a group of $m$ policyholders who are aged $x$ with the same risk characteristics, and whose survival probability distribution are independent and identical; the final age is $n$. The product is composed of an annuity, with annual payment $R$, and a GMDB option; there is a single premium, paid at time 0 and invested in a fund. Let $V_t$ be the value of the account at time $t$, which is linked to
a unit fund. Following the standard assumptions in the literature, we model the evolution of the account value as:

\[ dV_t = (\mu - \eta)V_t dt + \sigma V_t dW_t \]

(1)

where \( W_t \) is a standard Brownian motion under the real probability space, \( \eta \) is the drift rate, \( \delta \) is the charge paid for the GMDB option. The risk neutral process for \( V_t \) is:

\[ dV_t = (r - \eta)V_t dt + \sigma V_t dW_t^Q \]

(2)

where \( r \) is the risk free rate and \( W_t^Q \) is a Brownian motion under a new Girsanov transformed measure \( Q \).

The payoff of the GMDB option at the time \( t=\tau \) is:

\[ G_\tau = \max\{e^{g\tau}V_\tau, 0\}, 0 \leq \tau \leq n \]

(3)

where \( \tau \) is the stochastic time of death and \( g \) is the guaranteed rate.

The premium is calculated according to the equivalence principle:

\[ P = Ra_{n,i} + D_0 \]

(4)

where \( a_{n,i} \) is the actuarial value of an annuity, \( i \) is the technical rate used to price the annuity and \( D_0 \) is the value of the GMDB option at \( t=0 \) (see Haberman and Piscopo (2008)). Appendix A provides details on how to describe the GMDB payoff and calculate its expected value. VAs, like unit linked contracts, can be structured in different ways: both of the constituent living and death benefits or just one of them can be linked to a fund account. In our case, only the death benefit is invested in a fund and so the premium can be ideally decomposed into a sterling part and a unit part:

\[ P = P' + P'' \]

(5)

where \( P' \) is the sterling part, relating to the annuity, and \( P'' \) is the unit part, relating to the GMDB option and which is invested in a fund.

Let \( r \) be a valuation date at which we estimate the surplus linked to this contract.

Let \( RC_j^{(r)} \) be the net cash flow at time \( j \) for \( 0 \leq j \leq r \); it is called retrospective cash inflow at time \( r \). It is given by:
\[
RC_{j}^{(r)} = \sum_{i=1}^{m} \left[ P_{i,i}^{(j=0)} - R \alpha_{i,j}^{1/(j=0)} - G_{j} \delta_{i,j}^{1/(j=0)} \right] =
\]
\[
= mP_{i,i}^{(j=0)} - R \left( \sum_{i=1}^{m} \alpha_{i,j}^{1/(j=0)} \right) - G_{j} \left( \sum_{i=1}^{m} \delta_{i,j}^{1/(j=0)} \right) =
\]
\[
= mP_{i,i}^{(j=0)} - R \alpha_{j}^{1/(j=0)} - G_{j} \delta_{j}^{1/(j=0)}
\]

where

\[
\alpha_{i,j} = \begin{cases} 
1 & \text{if policyholder } i \text{ is alive at time } j \\
0 & \text{otherwise}
\end{cases} ;
\]

\[
\delta_{i,j} = \begin{cases} 
1 & \text{if policyholder } i \text{ is dies in year } j \\
0 & \text{otherwise}
\end{cases}
\]

\(\alpha_{j}\) is the number of people from the initial group of \(m\) policyholder who survive to time \(j\) and \(\delta_{j}\) is the number of deaths in year \(j\). Let \(m_{r}\) be the size of the portfolio at time \(r\); for \(0 < j \leq n-r\) we have:

\[
\begin{align*}
\{ \alpha_{j} | \alpha_{r} = m_{r} \} & \approx \text{BIN}(m_{r}, j_{x+r}) \\
\{ \delta_{j} | \alpha_{r} = m_{r} \} & \approx \text{BIN}(m_{r}, j_{x+r})
\end{align*}
\]

We consider \(r=0\), since we study all cash flows as viewed from time 0. We have for \(k<j\):

\[
\begin{align*}
E_{0} [\alpha_{i,j}] & = m_{j} p_{x_{i}} \\
E_{0} [\delta_{i,j}] & = m_{j-1} q_{x_{i}} \\
\text{Var}_{0} [\alpha_{i,j}] & = m_{j} p_{x_{i}} (1 - j_{p_{x_{i}}}) \\
\text{Var}_{0} [\delta_{i,j}] & = m_{j-1} q_{x_{i}} (1 - j_{1} q_{x_{i}}) \\
\text{Cov}_{0} [\alpha_{i,k}, \alpha_{i,j}] & = m_{j} p_{x_{i}} (1 - k_{p_{x_{i}}}) \\
\text{Cov}_{0} [\delta_{i,k}, \delta_{i,j}] & = -m_{j-1} q_{x_{i}} \times k_{1} q_{x_{i}} \\
\text{Cov}_{0} [\delta_{i,j}, \alpha_{i,j}] & = -m_{j-1} q_{x_{i}} \times j_{p_{x_{i}}} \\
\text{Cov}_{0} [\delta_{i,k}, \alpha_{i,j}] & = -m_{k-1} q_{x_{i}} \times j_{p_{x_{i}}} \\
\text{Cov}_{0} [\alpha_{i,k}, \delta_{i,j}] & = m_{(1-k_{p_{x_{i}}})} j_{1} q_{x_{i}}
\end{align*}
\]

Calculation of the cash flow moments is straightforward. Under the reasonable assumption of independence between \(G_{j}\) and \(\delta_{j}\) or \(\alpha_{j}\) we have:

\[
E[RC_{j}^{(r)}] = mP_{i,i}^{(j=0)} - RE[\alpha_{j}]^{(j=0)} - E[G_{j}]E[\delta_{j}]^{(j=0)}
\]

(7)
where \( E[G_j] = E[\max(e^{S_j} V_o, V_j)] \) can be calculated by simulating the evolution of the fund value and the corresponding GMDB value.

Moreover, we can calculate the variance of the retrospective cash flow:

\[
\text{Var}[RC_j^r] = R^2 \text{Var}[\alpha_j] + \text{Var}[G_j \delta_j] + 2R \text{Cov}[\alpha_j, G_j \delta_j]
\]

and the covariance of the retrospective cash flows:

\[
\text{Cov}[RC_k^r, RC_j^r] = R^2 \text{Cov}[\alpha_k, \alpha_j] + \text{Cov}[G_k \delta_k, G_j \delta_j] + R \text{Cov}[\alpha_k, G_k \delta_j] + R \text{Cov}[\alpha_j, G_k \delta_k]
\]

Now we fix our attention on the time period after \( r \). Let \( PC_j^r \) be the net cash flow plus the value of the shares invested in the fund that occurs \( j \) time units after \( r \) for \( 0 \leq j \leq n-r \), where \( n \) is the final age underlying the life table; this is called the prospective cash outflow at time \( r \). It is given by:

\[
PC_j^r = \sum_{i=1}^{m} [R \alpha_{i(r+j)} 1_{\{j=0\}} + G_{r+j} \delta_{i(r+j)} 1_{\{j=0\}}] =
\]

\[
= R \left( \sum_{i=1}^{m} \alpha_{i(r+j)} \right) 1_{\{j=0\}} + G_{r+j} \left( \sum_{i=1}^{m} \delta_{i(r+j)} \right) 1_{\{j=0\}}
\]

We can derive formulae for the moments of the cash flow in the same manner as before.

\[
E[PC_j^r] = RE[\alpha_{r+j}] + E[G_{r+j}] E[\delta_{r+j}]
\]

\[
\text{Var}[PC_j^r] = R^2 \text{Var}[\alpha_{r+j}] + \text{Var}[G_{r+j} \delta_{r+j}] + 2R \text{Cov}[\alpha_{r+j}, G_{r+j} \delta_{r+j}]
\]

Next, we introduce two random variables, the retrospective gain and the prospective loss, which will be used to define the surplus.

### 3. Retrospective gain, prospective loss and surplus

The retrospective gain at time \( r \) is the difference between the accumulated value to time \( r \) of past premiums collected and benefits paid. It can be expressed in terms of \( RC_j^r \) as follows:

\[
RG_r = \sum_{j=0}^{r} RC_j^r e^{I_j}
\]

where \( I(s,r) \) denotes the force of interest accumulation function between times \( s \) and \( r \) if \( 0 \leq s \leq r \) and the force of interest actualization function if \( r \leq s \leq n-r \); it is given by:
\[ I(s, r) = \begin{cases} 
\sum_{j=s+1}^{r} \lambda(j) & \text{if } s < r \\
0 & \text{if } s = r \\
-\sum_{j=s}^{r-1} \lambda(j) & \text{if } s > r 
\end{cases} \]

and \( \lambda(j) \) is the force of interest in period \((j-1,j]\). It is reasonable to assume independence between the fund value and interest rate. Thus, we obtain:

\[ E[RG_r] = \sum_{j=0}^{r} E[RC_j^r]E[e^{I(j,r)}] \]  \hspace{1cm} (15)

\[ Var[RG_r] = E[RG_r^2] - [E[RG_r]]^2 = \sum_{k=0}^{r} \sum_{j=0}^{r} E[RC_k^r RC_j^r]E[e^{I(k,r)+I(j,r)}] - \left( \sum_{j=0}^{r} E[RC_j^r]E[e^{I(j,r)}] \right)^2 = \] \hspace{1cm} (16)

The prospective loss at time \( r \) is the difference between the discounted values to time \( r \) of future benefits to be paid and premiums to be collected (although, in this case, there are no future premiums since the contract has a single premium at time 0). The prospective loss can be expressed in terms of \( PC_j^{(r)} \) as follows:

\[ PL_r = \sum_{j=0}^{n-r} PC_j^{(r)}e^{I(r,r+j)} \] \hspace{1cm} (17)

The moments of \( PL_r \) can be calculated in a similar way to the moments of \( RG_r \).

At this point of the analysis, we define the net stochastic surplus as the difference between the retrospective gain and the prospective loss:

\[ S_r = RG_r - PL_r = \sum_{j=0}^{n} FC_j^r e^{I(j,r)} \] \hspace{1cm} (18)

where \( FC_j^r \) is the generic cash flow (outflow or inflow) at time \( j \).

Thanks to our previous results, we can calculate the expected value and variance of surplus per policy:

\[ E[S_r / m] = E[RG_r / m] - E[PL_r / m] = \frac{1}{m} \sum_{j=0}^{n} E[FC_j^r]E[e^{I(j,r)}] \] \hspace{1cm} (19)
\[ Var[S_{r}/m] = Var\left[ \frac{\sum_{j=0}^{n} FC_{j} e^{I(j,r)}}{m} \right] = \]
\[ = \frac{1}{m^2} \left( \sum_{j=0}^{n} Var[FC_{j} e^{I(j,r)}] + \sum_{j=0}^{n} \sum_{k=0}^{n} \sum_{k \neq j} Cov(FC_{j} e^{I(j,r)}, FC_{k} e^{I(k,r)}) \right) \]  
(20)

In Appendix B, we develop the above formulae.

4. Financial hypothesis

In accordance with the Black & Scholes’ framework, we model the evolution of the unit fund as in (1):
\[ dV_{t} = (\mu - \eta)V_{t}dt + \sigma V_{t}dW_{t} \]
(21)

Since \( W_{t} \) is a standard Brownian motion, it follows that:
\[ E_{0}[V_{t}] = V_{0} \exp\{(\mu - \eta)j\} \]
\[ E_{0}[V_{t}^2] = V_{0}^2 \exp\{2(\mu - \eta)j + \sigma^2 j\} \]
\[ E_{0}[G_{j}] = E\left[ \text{Max}(e^{\sigma V_{0}}, V_{j}) \right] = \text{Max}(e^{\sigma V_{0}}, E_{0}[V_{j}]) \]
\[ Var[G_{j}] = Var[V_{j}] \]
\[ Cov[G_{j}, G_{k}] = Cov[V_{j}, V_{k}] = 0 \]

Moreover, we model the force of interest by a conditional autoregressive process AR(1), given the force of interest at time zero. This model is considered by Bellhouse and Panjer (1981) and Marceau and Gaillardetz (1999). Let \( \delta(t) \) the force of interest in the period \( (t-1, t] \):
\[ \delta(t) - \delta = \varphi[\delta(t-1) - \delta] + \gamma \varepsilon(t) \]

Where \( \{\varepsilon(k)\} \) is a sequence of independent and identically distributed standard normal variables and \( \delta \) is the long term mean of the process. We assume \( |\varphi| < 1 \) to ensure the process is stationary in covariance. The moment of the accumulation function are derived in Cairns and Parker (1997).

We assume the independence between the fund and the forces of interest.

5. Numerical Results: the first two moments of the Surples

In this section, we apply the model and show numerical results for a portfolio of identical Variable Annuities with a GMDB option. We consider a group of 1000 policyholders aged 50 with the same risk characteristics, whose survival probability distributions are independent and identically. The mortality table used in our calculation is the SIM2002 based on the Italian male population, with the maximum age \( n=110 \). We set \( R=1 \) and \( i=0.04 \); under this hypothesis, the premium calculated
according to the equivalence principle is equal to 17; where, the sterling part $P = a_{110-50}$ is equal to 16 and the unit part $P = D = V$ is equal to 1. We set

</tbody>
</table>

$\sigma^2 = 0.03$

$\mu - \eta = 0.06$

$G = 0.04$

We have carried out 100000 simulations. We evaluate the first 2 moments of the surplus at different dates $r$ and show the results in Figures 1:

![Figure 1: Expected Value and variance of the Surplus per policy](image)

We note that, as the valuation date increases, the standard deviation of the surplus increases. In order to understand this, we have to consider that the standard deviation of the surplus is affected by the uncertainty about the cash flows following the premium and by the variance of the interest rate. When $r$ increases, we have to accumulate a greater number of retrospective cash flows for a longer time and discount a smaller number of prospective cash flows for a shorter period. Consequently, the variance of the capitalized cash gains increases and that of the discounted losses decreases. Numerical investigation shows that the first effect prevails over the second one.

### 6. Distribution Function of Surplus: a stochastic approach

In the previous section, we have studied the first two moments of the stochastic surplus for a homogeneous portfolio of Variable Annuity contracts with GMDB options. Although the analysis of moments is useful, it is only the first step towards exploring the random behaviour of the surplus. We note that the standard deviation as a risk measure is inappropriate when dealing with asymmetric distributions and it is necessary to study the whole probability function of surplus.
Lysenko and Parker (2007) suggest a recursive method to construct this distribution; the complexity of the product we are considering makes necessary a simulation approach.

One of the objectives of this study is to assess the probability of insolvency, i.e. the probability that it will fall below zero. In order to achieve this purpose, we simulate the evolution of surplus under a mortality and financial stochastic model. Unlike the approach of Lysenko and Parker (2007), we do not approximate the true probability function of surplus by its limiting distribution, which takes into account the investment risk but treats cash flows as given and equal to their expected value. Instead, in order to take account also the longevity risk, we simulate the impact of both financial and mortality factors on retrospective gains and prospective losses.

The financial assumptions are the same as described previously. Also, we need a mortality assumption in order to avoid underestimation or overestimation of the surplus. In this respect, we consider the stochastic model suggested by Cox and Lin (2005) and developed by Ballotta, Esposito and Haberman (2006) and which is described below.

Our calculation is based on the actuarial table used before; however, we estimate the expected value of the number of survivors at age \( x + t \), \( E[l(x+t)] \), in a stochastic framework. It is possible to prove that \( l(x+t) \) is approximately distributed as a normal random variable with mean equal to \( l(x) \cdot p_x \) and variance equal to \( l(x) \cdot p_x (1 - p_x) \). However, the recent actuarial literature highlights the fact that the empirical data show perturbations in survival probabilities due to random shocks. Accordingly, we simulate the survival probabilities adjusted for shocks as follows:

\[
p'_{x+t} = p_{x+t} (1 - \varepsilon_t)
\]  

(22)

where \( \varepsilon_t \) is the shock in the expected probability at time \( t \). Ballotta, Esposito and Haberman (2006) assume that \( \varepsilon_t \) follows a beta distribution with parameter \( a \) and \( b \) and the sign of the shocks depends on the random number \( k(t) \) simulated from the uniform distribution \( U(0,1) \). In particular, we set:

\[
\begin{align*}
    \varepsilon(t) \quad & \text{if} \quad k(t) < c \\
    -\varepsilon(t) \quad & \text{if} \quad k(t) \geq c
\end{align*}
\]

where \( c \) is a parameter which depends on the expectation of future mortality trend.

The importance of assigning a random sign to \( \varepsilon_t \) is that, in this way, the model captures not only the long period variations in mortality rates, but also the short period fluctuations due to exceptional circumstances.

We carry out 100000 simulations under different financial and mortality hypotheses. The results are shown in three sections concerning interest rate risk, fund risk and mortality risk.

**a. Interest Rate Risk: Numerical Results**

We construct the distribution of the surplus per policy at different valuation dates under the hypothesis of the previous section. Results are shown in Figure 2 and summarized in Table 1:
We want to verify what happens under a different scenario for the force of interest. In particular, we investigate the effect of a reduction in the long mean of the force of interest. We compare the distribution of the Surplus per policy at the valuation date $r=1$ under the following scenarios:

<table>

</tbody>
</table>

**Table 2: Probability of Insolvency and significant percentile of the surplus distribution**

This comparison highlights the importance of a correct investment strategy in order to avoid the insolvency. In this case, the insurer has to invest the collected premiums into assets with a long mean of the rate of return equal to 0.06 in order to have a positive surplus since the first year and not ask other money to shareholders. We note that if the insurer invests the premiums into assets that in mean yield a return equal to the guaranteed rate on GMDB the probability of insolvency at r=1 is 64.35%.
b. Fund Risk: Numerical Results

In this section, we study the effect of shifts in the distributions of fund value. As we wish to produce a sensitivity analysis, we fix the hypothesis concerning the interest rate distribution according the parameters used in section 5 and change those concerning the fund. In particular, we compare the surplus distributions under the following four scenarios:

<table>
<thead>
<tr>
<th>Scenario</th>
<th>I</th>
<th>II</th>
<th>III</th>
<th>IV</th>

Table 3: Summary indices of the surplus distribution per policy under different scenarios

As expected, as the volatility of the fund increases the variance of the surplus increases and as the guaranteed rate increases the mean of the surplus distribution decreases. Moreover, as the drift of the fund process decreases, the distribution of the surplus moves on the right, as shown in Figure 4, because the amounts of death benefits paid decrease.

![Figure 4: the distribution of surplus per policy under two different hypothesis for the fund process.](image-url)
c. Mortality Risk: Numerical Results

In this section, we study the effect of shifts in the parameters of stochastic mortality model. In the same manner as the previous sections, we aim to produce a sensitivity analysis, and so we fix the hypothesis concerning the interest rate and the fund evolution as in section 5 and change the mortality table. In particular, we use the mortality model described and set \( a=0.5 \) and \( b=4.5 \). we evaluate the surplus per policy at \( r=30 \). We consider three cases for the value of \( c \): \( c = 0, 0.5, 1 \). In the first case, there will be improvements in life expectancy at every date; in other words, all of the shocks are expected to be positive. Conversely, in the second case further improvements of an already high expectancy of life are impossible and all shocks are expected to be negative.

Under the hypothesis \( c=1 \), the outflows linked to annuities increase and, under the hypothesis \( c=0 \), they decrease. In Figure 16, we show the cdf of the number of deaths that occur in each year under the hypotheses \( c=0, c=0.5 \) and \( c=1 \). Under the hypothesis \( c=0 \), the pdf of the number of deaths is translated to the left and it has a fatter left tail and a less fat right tail than the other two curves. On the contrary, if \( c=1 \) the pdf of the number of deaths is translated to the right and it has a less fat left tail and a fatter right tail than the other two curves.

![Figure 5: Pdf of the number of deaths under the hypotheses c=0, c=0.5 and c=1.](image)

As \( c \) increases, the outflows linked to the annuity increase; moreover, the payments related to the GMDB option increase too, because they are rolled over and they are linked to a fund value that increases with time. Consequently, the cumulative distribution of the surplus moves on the left and the probability of insolvency increases. These results are illustrated in Figure 6 and Table 4.

---

2 Figure 5 shows an unusual feature: each curve has two modes. The 2-modal feature can be found also in a recent Belgian males table (see Pitacco et al. (2008)).

7. Conclusions

The surplus is an important indicator of an insurance company’s financial position and there exists a considerable actuarial literature on the topic (see, for example, Coppola et al. (2003), Hoedemakers et al. (2005), Lysenko and Parker (2007), Marceau and Gaillardetz (1999) and Parker (1996)). The contribution of this paper has been to analyze the behaviour of the insurance surplus for a portfolio of Variable Annuities with GMDB options. In order to achieve this purpose, we have simulated the evolution of the surplus under a mortality and financial stochastic model. The results are presented on the basis of a simplified model; thus, the cash flows arise from the benefit and premium payment streams and are assumed to be dependent only on the mortality experience of the portfolio so that
expenses and lapse options are not considered; and further random lifetimes and rates of return are assumed to be independent. These are limitations of our framework and in subsequent work the model will be improved by introducing a more complex and realistic model structure and assumptions.

Despite the above limitations, we believe that the paper is useful in enhancing an insurer’s understanding of the stochastic behaviour underlying a Variable Annuity product with a GMDB option and that it provides the first study of the surplus in respect of this recently developed insurance product. Indeed, up to this time, the literature has offered only pricing models for GMDB, but has not studied the evolution of cash flows. We deem this consideration is important in the perspective of the liquidity and insolvency risk management. We have considered both financial and mortality risk and have outlined a comprehensive description of the interaction of different risk factors on the GMDB value. As a general rule, if a death benefit is added to an annuity, there is a sort of “mortality natural hedging effect”, i.e. the impact of longevity risk is reduced because the annuity is paid for a longer period but the actual value of the death benefit decreases. The GMDB options can represent an exception to this rule; in section 6.3 we have shown that as the estimated life extends the outflows linked to the annuity increase and at the same time the payments related to the GMDB option increase too, because they are rolled over and they are linked to a fund value that increases with time. Therefore, under the hypothesis of a growing fund, the effect of “natural hedging” is nullified. Hence, it is not sufficient to study the impact of each risk factor on the GMDB value, but it is necessary to examine their interaction.

In the paper, numerical examples show a significant impact of the interest, fund and mortality risks on the surplus distribution, insomuch as the insolvency probability increases considerably in many cases. With regard to this point, an advantage of the model used is that it allows an ex ante assessment of the insurer’s solvency throughout the duration of contract. Consequently, a change to the design of the product can be made, and, in particular, the premium can be modified according to the forecasts of mortality probabilities, interest rate and fund evolution. Moreover, the model enables us to determine the premium that leads to a required probability of insolvency, and so it can be used for an evaluation of the adequacy of solvency, which is consistent with recent regulatory changes.

References

APPENDIX A

Let T be the future lifetime random variable expressed in continuous time, F_x(t) be its cdf and f_x(t) be its pdf; therefore, for an individual aged x the probability of death before time t is

\[ F_x(t) = P(T \leq t) = 1 - e^{-\int_0^t \zeta(x+s)ds} \]

where \( \zeta \) denotes the force of mortality.

Let \( V_t \) be the account value at time t linked to fund value. Following standard assumptions in the literature, we model the evolution of the account as:

\[ dV_t = (\mu - \eta)V_t dt + \sigma V_t dW_t \]

where \( W_t \) is a standard Brownian motion, \( \mu \) is the drift rate, \( \eta \) is the charge paid for the GMDB option.

The risk neutral process for \( V_t \) is:

\[ dV_t = (r - \eta)V_t dt + \sigma V_t dW^Q_t \]

where \( r \) is the risk free rate and \( W^Q_t \) is a Brownian motion under a new Girsanov transformed measure \( Q \). The solution of the SDE is:

\[ V_t = V_0 e^{(r-\eta-\sigma^2/2)t + \sigma W^Q_t} \]

Now we describe the GMDB payoff. At the random date of death \( \tau \) the beneficiary will receive

\[ D_\tau = \max(e^{g\tau}V_0, V_\tau) = e^{g\tau} \max(V_0 - e^{-g\tau}V_\tau, 0) + V_\tau \]

where \( g \) is the guaranteed rate.

The value of the GMDB option at \( \tau \) is the sum of the fund value and a put option whose strike price is the initial value \( V_0 \), with an underlying asset \( V_\tau \) discounted by the guaranteed growth rate \( g \). Since the maturity is stochastic and \( \tau \) and \( V_\tau \) are independent, the present value of GMDB is given by the expectations under \( \tau \) and \( V_\tau \):

\[ D_0^P = E_\tau \{ E^Q \{ e^{-r\tau} D_\tau \mid \tau = t \} \} \]

If we fixed the date \( \tau \), we have at \( \tau \) an European Option, whose actual value can be calculated with Black and Scholes formula. Therefore, the previous formula can be interpreted as a decomposition of the actual value of GMDB in the actual value of a continuous sequence of European put option. Substituting the expression of \( D_\tau^P \)
\[ D_0^p = E_t \left[ E^Q \left\{ e^{-(r-g)\tau} \max(V_0 - e^{-g\tau}V_\tau, 0) + e^{-r\tau}V_\tau \mid \tau = t \right\} \right] \]

We can observe that
\[ E^Q \left\{ e^{-r\tau}V_\tau \right\} = e^{-\eta\tau}V_0 \]

since we have assumed that \( V_t \) is a geometric Brownian motion with drift equal to \( r-\delta \) and so its expected value is:
\[ E^Q_{(0)} \{ V_\tau \} = e^{(r-\eta)\tau}V_0 \]

Consequently:
\[ D_0^p = E_t \left[ E^Q \left\{ e^{-(r-g)\tau} \max(V_0 - e^{-g\tau}V_\tau, 0) + e^{-r\tau}V_\tau \mid \tau = t \right\} \right] = \]
\[ = E_t \left[ E^Q \left\{ e^{-(r-g)\tau} \max(V_0 - e^{-g\tau}V_\tau, 0) + e^{-r\tau} \mid \tau = t \right\} \right] \]

We observe that for a fixed date \( T \)
\[ E^Q \left\{ e^{-(r-g)\tau} \max(V_0 - e^{-g\tau}V_T, 0) + e^{-r\tau} \right\} = \]
\[ = V_0 \left[ e^{-r\tau}N(-d_2) - e^{-\eta\tau}N(-d_1) + e^{-r\tau} \right] = \]
\[ = V_0 \left[ BS \left( \tilde{r}, \eta, \sigma, T \right) + e^{-r\tau} \right] \]

where \( d_1 = \frac{\tilde{r} - \eta + \sigma^2 / 2}{\sigma} \sqrt{T} ; \quad d_2 = d_1 - \sigma \sqrt{T} ; \quad \tilde{r} = r - g ; \quad N(.) \) is the cumulative probability function for a random variable normally distributed.

If we consider both the expectations:
\[ D_0^p = \int_{0}^{\omega-x} f \left( t \right) V_0 \left[ BS \left( \tilde{r}, \eta, \sigma, t \right) + e^{-\tilde{r}t} \right] dt \]

In the discrete case we have:
\[ D_0^p = \sum_{t=1}^{\omega-x} p(t) q_{x+t} V_0 \left[ BS \left( \tilde{r}, \eta, \sigma, t \right) + e^{-\tilde{r}t} \right] \]

for a policyholder aged \( x \) at inception of the contract.

The value of GMDB is a weighted average of the values of \( \omega-x \) European put options, where the weights are the postponed probability of death in \( t \), i.e. the probability of survival until \( t \) and death between \( t \) and \( t+1 \).
APPENDIX B

The variance of the cash flows (both retrospective or prospective) is given by the following formula:

$$\text{Var}[FC_j] = R^2 \text{Var}[\alpha_j] + \text{Var}[G_j, \delta_j] + 2R \text{Cov}[\alpha_j, G_j, \delta_j]$$

where

- $$\text{Var}[G_j, \delta_j] = E[G_j^2 \text{Var}[\delta_j^2] - (E[G_j])^2 (E[\delta_j])^2]$$;
- $$\text{Cov}[\alpha_j, G_j, \delta_j] = E[G_j \text{Cov}[\alpha_j, \delta_j]]$$

in fact

The covariance of the cash flows is:

$$\text{Cov}[FC_k^{(\tau)}, FC_j^{(\tau)}] =$$

$$= R^2 \text{Cov}[\alpha_k, \alpha_j] + \text{Cov}[G_k, G_j, \delta_j] + R \text{Cov}[\alpha_k, G_j, \delta_j] + \text{Cov}[\alpha_j, G_k, \delta_k]$$

where

- $$\text{Cov}[G_k, G_j, \delta_j] = E[G_k G_j \delta_j] - E[G_k] E[G_j] E[\delta_j] =$$

  $$= E[G_k] E[G_j] \text{Cov}[\delta_k, \delta_j]$$

- $$\text{Cov}[\alpha_k, G_j, \delta_j] = E[G_j \text{Cov}[\alpha_k, \delta_j]]$$

- $$\text{Cov}[\alpha_j, G_k, \delta_k] = E[G_k \text{Cov}[\alpha_j, \delta_k]]$$

Finally, the variance of the surplus can be calculated:
\[ Var[S_r/m] = \frac{1}{m^2} \sum_{j=0}^{n} \left[ \sum_{j=0}^{n} Var[FC_j e^{I(j,r)}] \right] + \sum_{j=0}^{n} \sum_{k \neq j} Cov(FC_j e^{I(j,r)}, FC_k e^{I(k,r)}) \]

- \[ Var[FC_j e^{I(j,r)}] = \]
\[ = E[FC_j^2 e^{I(j,r)}^2] - \left( E[FC_j e^{I(j,r)}] \right)^2 = E[FC_j^2] E[e^{I(j,r)}^2] - E[FC_j]^2 E[e^{I(j,r)}]^2 = \]

- \[ Cov(FC_j e^{I(j,r)}, FC_k e^{I(k,r)}) = \]
\[ = E[FC_j FC_k e^{I(j,r)+I(k,r)}] - E[FC_j] E[e^{I(j,r)}] E[FC_k] E[e^{I(k,r)}] = \]
\[ = E[FC_j FC_k] E[e^{I(j,r)+I(k,r)}] - E[FC_j] E[e^{I(j,r)}] E[FC_k] E[e^{I(k,r)}] = \]
\[ = E[FC_j FC_k] Cov[e^{I(j,r)}, e^{I(k,r)}] - E[e^{I(j,r)}] E[e^{I(k,r)}] - E[FC_j] E[e^{I(j,r)}] E[FC_k] E[e^{I(k,r)}] \]
