We present a new genre classification framework using both low-level signal-based features and high-level harmony features. A state-of-the-art statistical genre classifier based on timbral features is extended using a first-order random forest containing for each genre rules derived from harmony or chord sequences. This random forest has been automatically induced, using the first-order logic induction algorithm TILDE, from a dataset, in which for each chord the degree and chord category are identified, and covering classical, jazz and pop genre classes. The audio descriptor-based genre classifier contains 206 features, covering spectral, temporal, energy, and pitch characteristics of the audio signal. The fusion of the harmony-based classifier with the extracted feature vectors is tested on three-genre subsets of the GTZAN and ISMIR04 datasets, which contain 300 and 448 recordings, respectively. Machine learning classifiers were tested using 5x5-fold cross-validation and feature selection. Results indicate that the proposed harmony-based rules combined with the timbral descriptor-based genre classification system lead to improved genre classification rates.

1. Introduction

Because of the rapidly increasing number of music files one owns or can access online, and given the variously reliable/available metadata associated with these files, the Music Information Retrieval (MIR) community has been working on automating the music data description and retrieval processes for more than a decade (Downie et al. 2009). One of the most widely investigated tasks is automatic genre classification (Lee et al. 2009). Although a majority of genre classification systems are signal-based – cf. (Scaringella et al. 2006) for an overview of these systems – they suffer from several limitations, such as the creation of false positive hubs (Aucouturier and Pachet 2008) and the glass-ceiling reached when using timbre-based features (Aucouturier and Pachet 2004). They also lack high-level and contextual concepts which are as important as low-level content descriptors for the human perception/characterisation of music genres (McKay and Fujinaga 2006). Recently, several attempts have been made to integrate these state-of-the-art low-level audio features with higher-level features, such as long-time audio features (Meng et al. 2005), statistical (Lidy et al. 2007) or distance-based (Cataltepe et al. 2007) symbolic features, text features derived from song lyrics (Neumayer and Rauber 2007), cultural features or contextual features extracted from the web (Whitman and Smaragdis 2002) or social tags (Chen et al. 2009) or combinations of several of these high-level features (McKay and Fujinaga 2006)¹.

Another type of high-level feature is concerned with musical concepts, such as harmony, which is used in this work. Although some harmonic (or chord) sequences are famous for being used by a composer or in a given genre, harmony is scarcely found in the automatic genre recognition literature as a means to that end. Tzanetakis et al. (2003),

¹Given the extensive literature on automatic music genre classification only one example for each kind of feature is cited here.
introduced pitch histograms as a feature describing the harmonic content of music. Statistical pattern recognition classifiers were trained to extract the genres. Classification of audio data covering 5 genres yielded recognition rates around 70%, and for audio generated from MIDI files rates reached 75%. However this study focuses on low-level harmony features. Only a few studies have considered using higher-level harmonic structures, such as chord progressions, for automatic genre recognition. In (Shan et al. 2002), a frequent pattern technique was used to classify sequences of chords into three categories: Enya, Beatles and Chinese folk songs. The algorithm looked for frequent sets, bi-grams and sequences of chords. A vocabulary of 60 different chords was extracted from MIDI files through heuristic rules: major, minor, diminished and augmented triads as well as dominant, major, minor, half and fully diminished seventh chords. The best two way classifications were obtained when sequences were used with accuracies between 70% and 84%. Lee (2007) considered automatic chord transcription based on chord progression. He used hidden Markov models on audio generated from MIDI and trained by genre to predict the chords. It turned out he could not only improve chord transcription but also estimate the genre of a song. He generated 6 genre-specific models, and although he tested the transcription only on the Beatles’ songs, frame rate accuracy reached highest level when using blues- and rock-specific models, indicating models can identify genres. Finally, Pérez-Sancho et al. have investigated whether stochastic language models including naïve Bayes classifiers and 2-, 3- and 4-grams could be used for automatic genre classification on both symbolic and audio data. They report better classification results when using a richer vocabulary (i.e. including seventh chords), reaching 3-genre classification accuracies on symbolic data of 86% with naïve Bayes models and 87% using bi-grams (Pérez-Sancho et al. 2009). To deal with audio data generated from MIDI they use a chord transcription algorithm and obtain accuracies of 75% with naïve Bayes (Pérez-Sancho 2009) and 89% when using bi-grams (Pérez-Sancho et al. 2010).

However, none of this research combines high-level harmony descriptors with other features. To our knowledge no attempt to integrate signal-based features with high-level harmony descriptors has been made in the literature. In this work, we propose the combination of low-level audio descriptors with a classifier trained on chord sequences which are induced from automatic chord transcriptions, in an effort to improve on genre classification performance using the chord sequences as an additional insight.

An extensive feature set is employed, covering temporal, spectral, energy, and pitch descriptors. Branch and bound feature selection is applied in order to select the most discriminative feature subset. The output of the harmony-based classifier is integrated as an additional feature into the aforementioned feature set which in turn is tested on two commonly used genre classification datasets, namely the GTZAN and ISMIR04. Experiments were performed using 5x5-fold cross-validation on 3-genre taxonomies, using support vector machines and multilayer perceptrons. Results indicate that the inclusion of the harmony-based features in both datasets improves genre classification accuracy in a statistically significant manner, while in most feature subsets a moderate improvement is reported.

The outline of the paper is as follows. The harmony-based classifier is presented in Section 2. In Section 3, a standard state-of-the-art classification system together with the fusion procedure employed for genre classification experiments are described. Section 4 briefly presents the datasets used and assesses the performance of the proposed fused classifier against the standard classifier. Conclusions are drawn and future directions are indicated in Section 5.
2. Learning Harmony Rules

Harmony is a high-level descriptor of music, focusing on the structure, progression, and relation of chords. As described by Piston (1987), in Western tonal music each period had different rules and practices of harmony. Some harmonic patterns forbidden in a period became common practices afterwards: for instance, the tritone was considered the diabolus in musica until the early 18th century and later became a key component of the tension/release mechanism of the tonal system. Modern musical genres are also characterised by typical chord sequences (Mauch et al. 2007). Like Pérez-Sancho et al. (2010), we base our harmony approach to music genre classification on the assumption that in Western tonal music (to which we limit our work) each musical period and genre exhibits different harmony patterns that can be used to characterise it and distinguish it from others.

2.1 Knowledge Representation

Characteristic harmony patterns or rules often relate to chord progressions, i.e. sequences of chords. However, not all chords in a piece of music are of equal significance in harmonic patterns. For instance, ornamental chords (e.g. passing chords) can appear between more relevant chords. Moreover, not all chord sequences, even when these ornamental chords are removed, can be typical of the genre of the piece of music they are part of: some common chord sequences are found in several genres, such as the perfect cadence (moving from the fifth degree to the first degree) which is present in all tonal classical music periods, jazz, pop music and numerous other genres. Thus, the chord sequences to look for in a piece of music as hints to identify and characterise its genre are sparse, can be punctuated by ornamental chords, might be located anywhere in the piece of music, and additionally, they can be of any length. Our objective is to describe these distinctive harmonic sequences of a style. To that end we adopt a context-free definite-clause grammar representation which proved to be useful for solving a structurally similar problem in the domain of biology: the logic-based extraction of patterns which characterise the neuropeptide precursor proteins (NPPs), a particular class of amino acids sequences (Muggleton et al. 2001).

In this formalism we represent each song as the list or sequence of chords it contains and each genre as a set of music pieces. We then look for a set of harmony rules describing characteristic chord sequences present in the songs of each genre. These rules define a Context-Free Grammar (CFG). In the linguistic and logic fields, a CFG can be seen as a finite set of rules which describes a set of sequences. Because we are only interested in identifying the harmony sequences characterising a genre, and not in building a comprehensive chord grammar, we use the concept of ‘gap’ (of unspecified length) between sub-sequences of interest to skip ornamental chords and non-characteristic chord sequences in a song, as done by Muggleton et al. (2001) when building their grammar to describe NPPs. Notice that like them, to automate the process of grammar induction we also adopt a Definite Clause Grammar (DCG) formalism to represent our Context-Free Grammars as logic programs, and use Inductive Logic Programming (ILP), which is concerned with the inference of logic programs (Muggleton 1991).

We represent our DCGs using the difference-list representation, and not the DCG representation itself, as this is what TILDE, the inference system we use, returns. In our formalist the letters of our alphabet are the chords labelled in a jazz/pop/rock shorthand fashion (e.g. G7, D♭, BM7, F♯m7, etc.). Properties of the chords are described using predicates (i.e. operators which return either true or false). In the difference-list representation these predicates take at least two arguments: an input list, and an output list. The predicate and the additional arguments (if there are any) apply to the difference be-
Figure 1.: A piece of music (i.e. list of chords) assumed to be in C major, and its Definite Clause Grammar (difference-list Prolog clausal) representation.

between the input list and the output list (which could be one or several elements). For instance, \texttt{degree} (1, \{cmaj7, bm, e7\}, \{bm, e7\}, cmajor) says that in the key of C major (last argument, \texttt{cmajor}) the chord Cmaj7 (difference between the input list \{cmaj7, bm, e7\} and the output list \{bm, e7\}) is on the tonic (or first degree, 1).

Previous experiments showed that the chord properties leading to the best classification results with our context-free grammar formalism are degree and chord category (Anglade et al. 2009b). So the two predicates that can be used by the system for rule induction are defined in the background knowledge:

- degrees (position of the root note of each chord relative to the key) and chord categories (e.g. min, 7, maj7, dim, etc.) are identified using the \texttt{degreeAndCategory}/5\(^1\) predicate;
- the \texttt{gap}/2 predicate matches any chord sequence of any length, allowing to skip uninteresting subsequences (not characterised by the grammar rules) and to handle large sequences for which otherwise we would need very large grammars.

Figure 1 illustrates how a piece of music, its chords and their properties are represented in our formalism.

2.2 Learning Algorithm

To induce the harmony grammars we apply the ILP decision tree induction algorithm TILDE (Blockeel and De Raedt 1998). Each tree built by TILDE is an ordered set of rules which is a genre classification model (i.e. which can be used to classify any new unseen song represented as a list of chords) and describes the characteristic chord sequences of each genre in the form of a grammar. The system takes as learning data a set of triples

\(^1/n\) at the end of a predicate represents its arity, i.e. the number of arguments it takes
Improving Music Genre Classification Using Harmony Rules

Anglade et al. 

(chord_sequence, tonality, genre), chord_sequence being the full list of chords present in a song, tonality being the global tonality of this song and genre its genre.

TILDE is a first order logic extension of the C4.5 decision tree induction algorithm (Quinlan 1993). Like C4.5 it is a top-down decision tree induction algorithm. The difference is that at each node of the trees conjunctions of literals are tested instead of attribute-value pairs. At each step the test (i.e. conjunction of literals) resulting in the best split of the classification examples\(^1\) is kept.

Notice that TILDE does not build sets of grammar rules for each class but first-order logic decision trees, i.e. ordered sets of rules (or Prolog programs). Each tree covers one classification problem (and not one class), so in our case rules describing harmony patterns of a given genre coexist with rules for other genres in the same tree (or set of rules). That is why the ordering of the rules we obtain with TILDE is an essential part of the classification: once a rule describing genre \(g\) is fired on an example \(e\) then \(e\) is classified as a song of genre \(g\) and the following rules in the grammar are not tested over \(e\). Thus, the rules of a model can not be used independently from each other.

In the case of genre classification, the target predicate given to TILDE, i.e. the one we want to find rules for, is \(genre/4\), where \(genre(g,A,B,Key)\) means the song \(A\) (represented as its full list of chords) in the tonality \(Key\) belongs to genre \(g\). The output list \(B\) (always an empty list), is necessary to comply with the definite-clause grammar representation. We constrain the system to use at least two consecutive degreeAndCategory predicates between any two gap predicates. This guarantees that we are considering local chord sequences of at least length 2 (but also larger) in the songs.

Here is an example in Prolog notation of a grammar rule built by TILDE for classical music (extracted from an ordered set containing rules for several genres):

\[
\text{genre(classical,A,Z,Key)} :- \\
\text{gap(A,B), degreeAndCategory(2,7,B,C,Key),} \\
\text{degreeAndCategory(5,maj,C,D,Key),} \\
\text{gap(D,E), degreeAndCategory(1,maj,E,F,Key),} \\
\text{degreeAndCategory(5,7,F,G,Key), gap(G,Z).}
\]

Which can be translated as: “Some classical music pieces contain a dominant 7th chord on the supertonic (II) followed by a major chord on the dominant, later (but not necessarily directly) followed by a major chord on the tonic followed by a dominant 7th chord on the dominant”.

Or: “Some classical music pieces can be modelled as: ... II7 - V ... I - V7 ...”.

Thus, complex rules combining several local patterns (of any length greater than or equal to 2) separated by gaps can be constructed with this formalism.

Finally, instead of using only one tree to handle each classification problem we construct a random forest, containing several trees. A random forest is an ensemble classifier whose classification output is the mode (or majority vote) of the outputs of the individual trees it contains which often leads to improved classification accuracy (Breiman 2001). Like in propositional learning, the trees of a first-order random forest are built using training sub-datasets randomly selected (with replacement) from the classification training set and no pruning is applied to the trees. However, when building each node of each tree in a first-order random forest, a random subset of the possible query refinements is considered (this is called query sampling), and not a random subset of the attributes as when building propositional random forests (Assche et al. 2006).

---

\(^1\) As explained in (Blockeel and De Raedt 1998) “the best split means that the subsets that are obtained are as homogeneous as possible with respect to the classes of the examples”. By default TILDE uses the information gain-ratio criterion (Quinlan 1993) to determine the best split.
2.3 Training Data

The dataset used to train our harmony-based genre classifier has been collected, annotated and kindly provided by the Pattern Recognition and Artificial Intelligence Group of the University of Alicante, and has been referred to as the Perez-9-genres Corpus (Pérez-Sancho 2009). It consists of a collection of 856 Band in a Box\textsuperscript{2} files (i.e. symbolic files containing chords) from which audio files have been synthesised, and covers three genres: popular, jazz, and classical music. The Popular music set contains pop (100 files), blues (84 files), and celtic music (99 files); jazz consists of a pre-bop class (178 files) grouping swing, early, and Broadway tunes, bop standards (94 files), and bossanovas (66 files); and classical music consists of Baroque (56 files), Classical (50 files) and Romantic Period music (129 files). All the categories have been defined by music experts, who have also collaborated in the task of assigning meta-data tags to the files and rejecting outliers.

In the merging experiments, involving both our harmony-based classifier and a timbre-based classifier, we use two datasets containing the following three genres: classical, jazz/blues and rock/pop (cf. Section 4.1). Since these classes differ from the ones present in the Perez-9-genres Corpus, we re-organise the latter into the following three classes, in order to train our harmony-based classifier on classes that match the testing datasets classes: classical (the full classical dataset from the Perez-9-genres Corpus, i.e. all the files from its 3 sub-classes), jazz/blues (a class grouping the blues and the 3 jazz subgenres from the Perez-9-genres Corpus) and pop (containing only the pop sub-class of the popular dataset from the Perez-9-genres Corpus). Thus we do not use the celtic subgenre.

2.4 Chord Transcription Algorithm

To extract the chords from the synthesised audio dataset, but also from the raw audio files on which we want to apply the harmony-based classifier, an automatic chord transcription algorithm is needed. We use an existing automatic chord labelling method, which can be broken down into two main steps: generation of a beat-synchronous chromagram and an additional beat-synchronous bass chromagram, and an inference step using a musically motivated dynamic Bayesian network (DBN). The following paragraphs provide an outline of these two steps. Please refer to (Mauch 2010, Chapters 4 and 5) for details.

The chroma features are obtained using a prior approximate note transcription based on the non-negative least squares method (NNLS). We first calculate a log-frequency spectrogram (similar to a constant-Q transform), with a resolution of three bins per semitone. As is frequently done in chord- and key- estimation (e.g. Harte and Sandler), we adjust this spectrogram to compensate for differences in the tuning pitch. The tuning is estimated from the relative magnitude of the three bin classes. Using this estimate, the log-frequency spectrogram is updated by linear interpolation to ensure that the centre bin of every note corresponds to the fundamental frequency of that note in equal temperament. The spectrogram is then updated again to attenuate broadband noise and timbre. To determine note activation values we assume a linear generative model in which every frame $Y$ of the log-frequency spectrogram can be expressed approximately as the linear combination $Y \approx E x$ of note profiles in the columns of a dictionary matrix $E$, multiplied by the activation vector $x$. Finding the note activation vector that approximates $Y$ best in the least-squares sense subject to $x \geq 0$ is called the non-negative least squares problem (NNLS).

We choose a semitone-spaced note dictionary with exponentially declining partials, and use the NNLS algorithm proposed by Lawson and Hanson (Lawson and Hanson 1974) to solve the problem and obtain a unique activation vector. For treble and bass chroma mapping we choose different profiles: the bass profile emphasises the low tone range, and the

\textsuperscript{2}http://www.pgmusic.com/products_bh.htm
treble profile encompasses the whole note spectrum, with an emphasis on the mid range. The weighted note activation vector is then mapped to the twelve pitch classes C,...,B by summing the values of the corresponding pitches. In order to obtain beat times we use an existing automatic beat-tracking method (Davies et al. 2009). A beat-synchronous chroma vector can then be calculated for each beat by taking the median (in the time direction) over all the chroma frames whose centres are situated between the same two consecutive beat times.

The two beat-synchronous chromagrams are now used as observations in the DBN, which is a graphical probabilistic model similar to a hierarchical hidden Markov model. Our DBN jointly models metric position, key, chords and bass pitch class, and parameters are set manually according to musical considerations. The most likely sequence of hidden states is inferred from the beat-synchronous chromagrams of the whole song using the BNT\(^1\) implementation of the Viterbi algorithm (Rabiner 1989). The method detects the 24 major and minor keys and 121 chords in 11 different chord categories: major, minor, diminished, augmented, dominant 7th, minor 7th, major 7th, major 6th, and major chords in first and second inversion, and a ‘no chord’ type. The chord transcription algorithm correctly identifies 80% (correct overlap, Mauch 2010, Chapter 2) of the chords in the MIREX audio data.

To make sure training and testing datasets would contain the same chord categories we apply the following post-processing treatments to our symbolic, synthesised audio and real audio datasets:

- Since they are not used in the symbolic dataset, after any transcription of synthesised audio or real audio we replace the major chords in first and second inversion with major chords, and the sections with no chords are simply ignored.
- Before classification training on symbolic data, the extensive set of chord categories found in the Band in a Box dataset is reduced to eight categories: major, minor, diminished, augmented, dominant 7th, minor 7th, major 7th, major 6th. This reduction is done by mapping each category to the closest one in term of both number of intervals shared and musical function.

Note however that the synthesised audio datasets are generated from the original Band in a Box files, so the ones containing the full set of chord categories and not the ones reduced to eight chords.
- Finally, in all datasets, repeated chords are merged to a single instance of the chord.

### 2.5 Learning Results

The performance of our harmony-based classifier was previously tested on both the full original symbolic Perez-9-genres Corpus, and automatic chord transcriptions of its synthesised version when using a single tree model (Anglade et al. 2009a,b), and not random forests as used here. For 3-way classification tasks, we reported a 5-fold cross-validation classification accuracy varying between 74% and 80% on the symbolic data, and between 58% and 72% on the synthesised audio data, when using the best parameters. We adopt the best minimal coverage of a leaf learned from these experiments: we constrain the system so that each leaf in each constructed tree covers at least five training examples. By setting this TILDE parameter to 5 we avoid any overfitting – as a smaller number of examples for each leaf means a larger number of rules and more specific rules – and in the same time it is still reasonable given the size of the dataset – a larger value would have been unrealistically too large for the system to learn any tree, or would have required a long computation time for each tree. We also set the number of trees in each random forest

\(^1\)http://code.google.com/p/bnt/
to thirty, since preliminary experiments showed it was a reasonable compromise between rather short computation time and good classification results. Query sampling rate is set to 0.25.

We evaluate our random forest model using again 5-fold cross-validation and obtain 3-genre classification accuracies of 87.7% on the full symbolic Perez-9-genres Corpus, and 75.9% on the full audio synthesised from MIDI Perez-9-genres Corpus. Notice that these results exceed those obtained with the naïve Bayes classifiers employed by Pérez-Sancho et al. in their experiments on the same dataset, and the symbolic results are comparable to those they obtain with their n-gram models.

We now simultaneously train our random forest classifier and estimate the best results it could obtain on clean and accurate transcriptions by performing a 5-fold cross-validation on the restricted and re-organised symbolic and synthesised audio dataset we created from the Perez-9-genres Corpus (cf. Section 2.3). The resulting confusion matrices\(^1\) are given in Table 1 and Table 2. The columns correspond to the predicted music genres and the rows to the actual ones. The average accuracy is 84.8% for symbolic data, and 79.5% for the synthesised audio data, while the baseline classification accuracy is 55.6% and 58%, when attributing the most probable genre to all the songs. The classifiers detects the classical and jazz/blues classes very well but only correctly classifies a small number of pop songs. We believe that this is due to the shortage of pop songs in our training dataset, combined with the unbalanced number of examples in each class: the jazz set is twice as large as the classical set which in turn is twice as large as the pop set. Performance of these classifiers on real audio data will be presented in Section 4.2.

\begin{table}[h]
\centering
\begin{tabular}{|c|c|c|c|}
\hline
Real/Predicted & classical & jazz/blues & pop & Total \\
\hline
classical & 218 & 15 & 1 & 234 \\
jazz/blues & 9 & 407 & 2 & 418 \\
pop & 26 & 61 & 13 & 100 \\
\hline
Total & 253 & 483 & 16 & 752 \\
\hline
\end{tabular}
\caption{Confusion matrix (test results of the 5-fold cross-validation) for the harmony-based classifier applied on the classical-jazz/blues-pop restricted and re-organised version of the Perez-9-genres Corpus (symbolic dataset).}
\end{table}

\begin{table}[h]
\centering
\begin{tabular}{|c|c|c|c|}
\hline
Real/Predicted & classical & jazz/blues & pop & Total \\
\hline
classical & 181 & 20 & 1 & 202 \\
jazz/blues & 34 & 373 & 1 & 408 \\
pop & 31 & 57 & 5 & 93 \\
\hline
Total & 246 & 450 & 7 & 703 \\
\hline
\end{tabular}
\caption{Confusion matrix (test results of the 5-fold cross-validation) for the harmony-based classifier applied on the classical-jazz/blues-pop restricted and re-organised version of the Perez-9-genres Corpus (synthesised audio dataset).}
\end{table}

\(^1\)Note that the total numbers of pieces in the tables do not match the total number of pieces in the Perez-9-genres Corpus:

- 5 files in the symbolic dataset have “twins”: i.e. different music pieces with different names which can be represented by the exact same list of chords. These twins are treated as duplicates by TILDE, which automatically removes duplicate files before training, and are thus not counted in the total number of pieces.
- A few files from the Perez-9-genres Corpus were not used in the synthesised audio dataset as they were unusually long files resulting in large memory allocations and long computation times when performing chord transcription.

#### 3. Combining Audio and Harmony-based Classifiers

In this section, a standard state-of-the-art classification system employed for genre classification experiments is described. The extracted features are listed in Section 3.1, the feature selection procedure is described in Section 3.2 and finally the fusion procedure is explained and the employed machine learning classifiers are presented in Section 3.3.

##### 3.1 Feature Extraction

In feature extraction, a vector set of numerical representations, that is able to accurately describe aspects of an audio recording, is computed (Tzanetakis and Cook 2002). Extracting features is the first step in pattern recognition systems, since any classifier can be applied afterwards. In most genre classification experiments the extracted features belong to 3 categories: timbre, rhythm, and melody (Scaringella et al. 2006). For our experiments, the feature set proposed in (Benetos and Kotropoulos 2010) was employed, which contains timbral descriptors such as energy and spectral features, as well as pitch-based and rhythmic features, thus being able to accurately describe the audio signal. The complete list of extracted features can be found in Table 3.

The feature related to the audio signal energy is the STE. Spectral descriptors of the signal are the SC, SRF, SS, SF, MFCCs, SD (also called spectral flux), and BW. Temporal descriptors include the AC, TC, ZCR, and PD. As far as pitch-based features are concerned, the FF feature is computed using maximum likelihood harmonic matching, while the PH describes the amplitude of the maximum peak of the folded histogram (Tzanetakis et al. 2003). The RP feature was proposed in (Pampalk et al. 2004). Finally, the TL feature and the SONE coefficients are perceptual descriptors which are based on auditory modeling.

All in all, 206 feature values are extracted for each sound recording. For the computation of the feature vectors, the descriptors are computed on a frame basis and their statistical
measures are employed in order to result in a compact representation of the signal characteristics. To be specific, their mean and variance are computed along with the mean and variance of the first-order frame-based feature differences over a 1 sec texture window. The same texture window size was used for genre classification experiments in (Tzanetakis and Cook 2002). Afterwards, the computed values are averaged for all the segments of the recording, thus explaining the factor 4 appearing in Table 3. This is applied for all extracted features apart from the AC values and the TC, which are computed for the whole duration of the recording. In addition, it should be noted that for the MFCCs, 24 coefficients are computed over a 10 msec frame (which is a common setting for audio processing applications), while 8 SONE coefficients are computed over the same duration – which is one of the recommended settings in (Pampalk et al. 2004).

### 3.2 Feature Selection

Although the extracted 206 features are able to capture many aspects of the audio signal, it is advantageous to reduce the number of features through a feature selection procedure in order to remove any feature correlations and to maximize classification accuracy in the presence of relatively few samples (Scaringella et al. 2006). One additional motivation behind feature selection is the need to avoid the so-called curse of dimensionality phenomenon (Burried and Lerch 2003).

In this work, the selected feature subset is chosen as to maximize the inter/intra class ratio (Fukunaga 1990). The aim of this feature selection mechanism is to select a set of features that maximizes the sample variance between different classes and minimizes the variance for data belonging to the same class, thus leading to classification improvement. The branch-and-bound search strategy is employed for complexity reduction purposes, being also able to provide the optimal feature subset. In the search strategy, a tree-based structure containing the possible feature subsets is traversed using depth-first search with backtracking (van der Hedjen et al. 2004).

For our experiments, several feature subsets were created, containing $\Theta = \{10, 20, \ldots, 100\}$ features. In Table 4, the subset for 10 selected features is listed, where it can be seen that the MFCCs and the SONE coefficients appear to be discriminative features.

### 3.3 Classification System

Figure 2 represents the steps that are performed to build our genre classification system. The proposed classifier combines the extracted and selected features presented in Sections
3.1 and 3.2 with the output of the harmony-based classifier described in Section 2. Considering the extracted feature vector for a single recording as $v$ (with length $\Theta$) and the respective output of the harmony-based classifier as $r = 1, \ldots, C$, where $C$ is the number of genre classes, a combined feature vector is created in the form of $v' = [v \ r]$. Thus, the output of the harmony-based classifier is treated as an additional feature used, along with the extracted and selected audio features, as an input to the learning phase of the overall genre classifier.

Two machine learning classifiers were employed for the genre classification experiments, namely multilayer perceptrons (MLPs) and support vector machines (SVMs). For the MLPs, a 3-layered perceptron with the logistic activation function was utilized, while training was performed with the back-propagation algorithm for learning rate equal to 0.3, 500 training epochs, and momentum equal to 0.1. A multi-class SVM classifier with a 2nd order polynomial kernel with unit bias/offset was also used (Schölkopf et al. 1999). The experiments with the aforementioned classifiers were conducted on the training matrix $V' = [v'_1 \ v'_2 \ \cdots \ v'_M]$, where $M$ is the number of training samples.

4. Experiments

4.1 Datasets

Two commonly used datasets in the literature were employed for genre classification experiments. Firstly, the GTZAN database was used, which contains 1000 audio recordings distributed across 10 music genres, with 100 recordings collected for each genre (Tzanetakis and Cook 2002). From the 10 genre classes, 3 were selected for the experiments, namely the classical, jazz, and pop classes. All recordings are mono channel, are sampled at 22.05 kHz rate and have a duration of approximately 30 sec.

The second dataset that was used was created for the ISMIR 2004 Genre Classification Contest (ISMIR 2004). It covers 7 genre classes, from which 3 were used: classical, jazz/blues, and pop/rock. The classical class contains 319 recordings, the jazz/blues class
26, and the pop/rock class 102. The duration of the recordings is not constant, ranging from 19 seconds to 14 minutes. The recordings were sampled at 22kHz rate and were converted from stereo to mono.

4.2 Results

First the harmony-based classifier (trained on both the re-organised symbolic and synthesised audio Perez-9-genres datasets) was tested on these two audio datasets. The results are shown in Table 5. For the GTZAN dataset, the classification accuracy using the harmony-based classifier is 41.67% (symbolic training) and 44.67% (synthesised audio training), while for the ISMIR04 dataset it is 57.49% (symbolic training) and 59.28% (synthesised audio training). Even though the classifier trained on synthesised audio data obtained worse results than the one trained on symbolic data when performing cross-validation on the Perez-9-genres datasets, the opposite trend is observed here when tested on the two real audio datasets. We believe the symbolic model does not perform as well on audio data because it assumes that the chord progressions are perfectly transcribed, which is not the case. The synthesised audio model on the other hand does account for this noise in transcription (and includes it in its grammar rules). Given these results we will use the classifier trained on synthesised audio data in the experiments merging the harmony-based and the audio feature based classifiers.

\[
\begin{array}{cccc}

\end{array}
\]

(d)

Table 5.: Confusion matrices for the harmony-based classifier trained on: (a) symbolic data and applied on the GTZAN dataset, (b) synthesised audio data and applied on the GTZAN dataset, (c) symbolic data and applied on the ISMIR04 dataset, (d) synthesised audio data and applied on the ISMIR04 dataset.
Then experiments using the SVM and MLP classifiers with 5x5-fold cross-validation were performed using the original extracted audio feature vector $v$ which does not include the output of the harmony-based classifier. First these classifiers were tested on the synthesised Perez-9-genres Corpus which is described in Section 2.3. The full set of 206 audio features was employed for classification. For the SVM, classification accuracy is 95.56%, while for the MLP classifier, the classification accuracy is 95.67%. While classification performance appears to be very high compared to the harmony-based classifier for the same data, it should be stressed that the Perez-9-genres dataset consists of synthesised MIDI files, making the dataset unsuitable for audio processing-based experiments. This happens because these files use different sets of synthesised instruments for each of the 3 genres, which produce unrealistic results when a timbral feature-based classifier is employed.

Finally, experiments comparing results of the SVM and MLP classifiers with and without the output of the harmony-based classifier (trained on synthesised audio data) were performed with the various feature subsets on the SVM and MLP classifiers using 5x5-fold cross-validation. The average accuracy achieved by the classifiers using 5x5-fold cross-validation for the various feature subset sizes using the GTZAN dataset is shown in Figure 3, while the average accuracy for the ISMIR04 dataset is shown in Figure 4. In Table 6 the best accuracy achieved for the various feature subsets and classifiers is presented. The SVM-H and MLP-H classifiers stand for the standard feature set $v$ (without harmony), while the SVM+H and MLP+H classifiers stand for the feature set $v'$ (with harmony).

For the GTZAN dataset, the highest classification accuracy is achieved by the SVM+H classifier using the 50 features subset, reaching 91.13% accuracy. The MLP classifiers seem to fall behind the SVM classifiers for the various feature subsets, apart from the subsets containing 70, 80, or 90 features. For the ISMIR04 dataset, the highest accuracy is also achieved by the SVM+H classifier, reaching 95.30% classification accuracy, for the 80 features subset. The SVM-H classifier reaches 93.77% rate for the same subset. In most cases, the SVM+H and MLP+H classifiers display increased classification
Figure 4.: Classification accuracy for the ISMIR04 dataset using various feature subsets.

rates over the SVM-H and MLP-H classifiers, respectively. There are however some cases where the classification rate is identical, for example for the MLP classifiers using the 60 features subset for the ISMIR04 dataset. The fact that the ISMIR04 rates are higher than the GTZAN rates can be attributed to the class distribution.

In order to compare the performance of the employed feature set with other feature sets found in the literature, the extracted features from the MARSYAS (Tzanetakis 2007) toolbox were employed, which contain the mean values of the spectral centroid, spectral rolloff, spectral flux, and the mean values of 30 MFCCs for a 1sec texture window. Results on genre classification using the MARSYAS feature set with 5x5-fold cross-validation on both datasets and using the same classifiers (SVM, MLP) and their respective settings can be seen in Table 7, where it can be seen that for the MLP classifier, the classification accuracy between the MARSYAS feature set and the employed feature set is roughly the same for both datasets. However, when the SVM classifier is used, the employed feature set outperforms the MARSYAS features by at least 3% for the GTZAN case and 4% for the ISMIR04 set. It should be noted however that no feature selection took place for the MARSYAS features.

Insight to the performance of the best cases of the various classifiers using both datasets is offered by confusion matrices determined by one classifier run using 5-fold cross-validation. The confusion matrices using the best SVM-H and SVM+H classifiers for the GTZAN and ISMIR04 datasets are presented in Table 8. For the GTZAN dataset most
misclassifications occur for the pop class, in both cases. However, the SVM+H algorithm rectifies some misclassifications of the pop class compared to the SVM-H classifier. For the ISMIR04 dataset, most misclassifications occur for the jazz/blues class for both classifiers. Even for the SVM+H classifier, when taking normalized rates, the jazz/blues class suffers the most, having only 63.58% correct classification rate. It should be noted though that the SVM+H classifier has 6 more jazz/blues samples correctly classified compared to the SVM-H one. The classical class on the other hand, seems largely unaffected by misclassifications.

Table 8.: Confusion matrices for one 5-fold cross validation run of: (a) the SVM-H classifier applied on the GTZAN dataset using the 60 selected features set, (b) the SVM+H classifier applied on the GTZAN dataset using the 50 selected features set, (c) the SVM-H classifier applied on the ISMIR04 dataset using the 70 selected features set, (d) the SVM+H classifier applied on the ISMIR04 dataset using the 80 selected features set.

Concerning the statistical significance of the proposed feature vector $v'$ compared to the performance of the standard feature vector $v$, the McNemar test (McNemar 1947)
was employed, which is applied to 2x2 contingency tables for a single classifier run. We consider the cases exhibiting the highest classification rates, as shown in Table 6. For the GTZAN dataset, the SVM-H classifier using the 60 features set is compared against the SVM+H classifier using the 50 features set. For the ISMIR04 dataset, the SVM-H classifier using 70 features is compared against the SVM+H classifier using 80 features. The contingency tables for the GTZAN and ISMIR04 datasets are respectively:

\[
\begin{array}{cc}
264 & 10 \\
2 & 24
\end{array}
\]  \quad \text{and}  \quad
\begin{array}{cc}
416 & 10 \\
3 & 18
\end{array}
\]  

(1)

The binomial distribution is used to obtain the McNemar test statistic, where for both cases the null hypothesis (the difference between the two classifiers is insignificant) is rejected with 95% confidence.

4.3 Discussion

This improvement of the classification results might come as a surprise when one considers that the harmony-based classifier by itself does not perform sufficiently well on audio data. Indeed on the ISMIR04 dataset its accuracy is lower than the baseline (59.28% vs. 71.36%). However, harmony is only one dimension of music which despite being relevant for genre identification can not capture by itself all genres’ specificities. The authors believe that the classification improvement lies in the fact that it covers an aspect of the audio-signal (or rather of its musical properties) that the other (low-level) features of the classifier do not capture.

In order to justify that the combination of several features improves classification accuracy even when they are lower than the baseline, the mean of the 5th MFCC was employed as an example feature. 5-fold cross-validation experiments were performed on the GTZAN and ISMIR04 datasets based on this single feature using SVMs. Results indicated that classification accuracy for the GTZAN dataset was 31.33%, while for the ISMIR04 dataset it was 71.36%, both of which are below the baseline. However the feature, being one of the selected ones, when combined with several other features manages to report a high classification rate as shown in Section 4.2. Thus, the inclusion of the output of the harmony-based classifier, while being lower than the baseline by itself, still manages to provide improved results when combined with several other descriptors. In addition, in order to compare the addition of the harmony-derived classification to the feature set with an additional feature, the Total Loudness (TL) was added into the SVM-H classifier using the 70 features subset (TL is not included in the set). Using the GTZAN dataset for experiments, classification accuracy for the 70 features subset is 82%, while adding the TL feature it increased by 0.66%, where the performance improvement is lower compared to the harmony-based classifier addition (which was 1.66%).

5. Conclusions

In the future, the combination of the low-level classifier with the harmony-based classifier can be expanded, where multiple features stemming from chord transitions can be combined with the low-level feature set in order to boost performance. In addition, the chord transition rules can be modeled to describe more genres, leading to experiments containing more elaborate genre hierarchies. This would allow to test how well our method scales.

In this work, an approach for automatic music genre classification was proposed, combining low-level features with a first-order logic random forest based on chord transitions
and built using the Inductive Logic Programming algorithm TILDE. Three-class genre classification experiments were performed on two commonly used datasets, where an improvement was reported for both cases when the harmony-based classifier was combined with a low-level feature set using support vector machines and multilayer perceptrons. The combination of these low-level features with the harmony-based classifier produces improved results despite the fact that the classification rate of the harmony-based classifier is not sufficiently high by itself. For both datasets when the SVM classifier was used, the improvement over the standard classifier was found to be statistically significant when the highest classification rate is considered. All in all, it was shown that the combination of high-level harmony features with low-level features can lead to genre classification accuracy improvements and is a promising direction for genre classification research.

6. Acknowledgements

This work was done while the third author was a Research Student at Queen Mary, University of London. This work is supported by the EPSRC project OMRAS2 (EP/E017614/1) and Emmanouil Benetos is supported by a Westfield Trust PhD Studentship (Queen Mary, University of London). The authors would like to thank the Pattern Recognition and Artificial Intelligence Group of the University of Alicante for providing the symbolic training dataset.
