Abstract

The impact of liquid droplets on solid surfaces at conditions inducing cavitation inside their volume has rarely been addressed in the literature. A review is conducted on relevant studies, aiming to highlight the differences from non-cavitating impact cases. Focus is placed on the numerical models suitable for the simulation of droplet impact at such conditions. Further insight is given from the development of a purpose-built compressible two-phase flow solver that incorporates a phase-change model suitable for cavitation formation and collapse; thermodynamic closure is based on a barotropic Equation of State (EoS) representing the density and speed of sound of the co-existing liquid, gas and vapour phases as well as liquid-vapour mixture. To overcome the known problem of spurious oscillations occurring at the phase boundaries due to the rapid change in the acoustic impedance, a new hybrid numerical flux discretization scheme is proposed, based on approximate Riemann solvers; this is found to offer numerical stability and has allowed for simulations of cavitation formation during drop impact to be presented for the first time. Following a thorough justification of the validity of the model assumptions adopted for the cases of interest, numerical simulations are firstly compared against the Riemann problem, for which the exact solution has been derived for two materials with the same velocity.

and pressure fields. The model is validated against the single experimental data set available in the literature for a 2-D planar drop impact case. The results are found in good agreement against these data that depict the evolution of both the shock wave generated upon impact and the rarefaction waves, which are also captured reasonably well. Moreover, the location of cavitation formation inside the drop and the areas of possible erosion sites that may develop on the solid surface, are also well captured by the model. Following model validation, numerical experiments have examined the effect of impact conditions on the process, utilising both planar and 2-D axisymmetric simulations. It is found that the absence of air between the drop and the wall at the initial configuration can generate cavitation regimes closer to the wall surface, which significantly increase the pressures induced on the solid wall surface, even for much lower impact velocities. A summary highlighting the open questions still remaining on the subject is given at the end.

**Keywords:** Cavitation, drop impact, approximate Riemann solvers, OpenFOAM

1. Introduction

Droplets impacting onto solid or liquid surfaces are of significant importance in many engineering applications, oceanography, food science and even forensics; see selectively [1, 2, 3, 4, 5, 6] among many others. For isothermal conditions, the Weber $We$, Reynolds $Re$, Ohnesorge $Oh$ and Froude $Fr$ numbers are frequently utilised to characterise the droplet impact outcome; these are defined as $We = \frac{\rho u_{imp}^2 D}{\sigma}$, $Re = \frac{\rho u_{imp} D}{\mu_l}$, $Oh = \frac{\sqrt{We}}{Re}$ and $Fr = \frac{u_{imp}}{\sqrt{gD}}$, respectively. In these relations, $u_{imp}$ is the impact velocity normal to the wall surface, $D$ is the droplet diameter, $\mu_l$ and $\rho_l$ are the dynamic viscosity and density of the liquid droplet respectively, $\sigma$ is the surface tension and $g$ is the gravitational acceleration. A number of post-impact outcomes are known for the normal/inclined impact of spherical droplets onto flat and smooth surfaces [7, 8]. In the vast majority among the cases of practical interest, the flow conditions and the evo-
olution of the droplet shape upon impact can be described assuming that the
liquid and the surrounding media behave as incompressible media. Still, out of
the very broad literature on the subject, or interest to the present paper are
the cases of impact at velocities of the order of $200\, m/s$ ($M \approx 0.6$ for air at
room temperature and atmospheric pressure) which are high enough for com-
pressibility effects to become important. Moreover, at such conditions pressure
waves developing within the liquid during impact may induce cavitation for-
motion within the droplet volume. Cavitation as a phenomenon involves the
formation of vaporous/gaseous cavities in the bulk of liquid, due to localized
static pressure drop. This can happen due to strong accelerations, high veloc-
ities or pressure waves. In the first case, cavitation is termed as 'hydrodynamic' and may occur in any device operating with liquids, e.g. propellers, turbines, pumps, valves etc. In the second case, cavitation is termed as 'acoustic', since it is induced by the presence or interaction of acoustic waves. Phase-change during cavitation is inertial driven [3] as opposed to phase-change processes driven by the temperature difference between the liquid, air and the solid surface. Moreover, for the high impact velocity conditions leading to cavitation formation, the impact outcome is expected to be in the splashing regime, where a corona is initially formed and gradually disintegrates into a number of droplet frag-
ments. Such impact velocities can be realised, for example, in steam turbines and aircraft components. The steam in the turbine engine operating at low pres-
sure conditions is prone to condensation and thus, water droplets are formed.
These droplets travel with the flow and can impact the turbine blades with high
speeds [2, 9]. The problem is further complicated by the subsequent cavitation formation and collapse induced by the pressure waves developing within the droplet’s volume. At such conditions, surface erosion and damage may occur, not only because of the impact pressure, but also due to the pressure increase occurring during the collapse of the cavitation bubbles. The early experimental work of Field et al. [10] documented that the edge pressures depend on the impact velocity and the angle between the liquid and the solid surfaces (see also [11]). More recently, Field et al. [12] presented high-speed images of impacted
liquids using several different techniques. By adding gelatine in the water, they
produced 2-D planar 'droplets' between two transparent plates while impact
was achieved by a projected third plate. The shock waves produced and the
resulting vapour formation due to cavitation within the bulk of liquid has been
observed qualitatively. So far, no other studies are known in this field. The
present paper aims to contribute to this area by conducting initially a literature
review on the subject, followed by numerical simulations from a purpose-built
computational model. The literature review starts with a summary of relevant
numerical works for droplet impact of incompressible liquids. Then a short
review on phase-change models and numerical methodologies for cavitation, rel-
relevant to the current study is included, followed by a review of the studies that
have addressed the role of compressibility during droplet impact. As already
mentioned, in the absence of computational studies in the literature for droplet
impact in the presence of cavitation formation and subsequent collapse, the pa-
paper presents results from a newly developed computational fluid dynamics flow
solver suitable for such conditions. Following validation against the experiments
of [12], parametric studies aim to provide further inside on the problem physics.

2. Literature Review

2.1. Summary of methodologies applied to droplet impact assuming incompress-
able liquids

Both experiments and complex numerical simulations based on the solution
of the Navier-Stokes equations have been utilised to characterise the impact
process of liquid droplet onto solid or liquid surfaces. Within the context of in-
compressibility and at conditions that surface tension (i.e. sufficiently small We
numbers) dominates the temporal development of the phenomenon, Lagrangian
(interface tracking) and Eulerian (interface capturing) approaches, or even a
combination of the two have been utilised to simulate the process. For example,
Harlow and Shannon [13] where the first to utilise the Lagrangian approach using
a marker-and-cell (MAC) finite difference algorithm ignoring surface tension
and viscosity, while the volume of fluid (VOF) model was introduced by Hirt and Nichols [14]; later Youngs [15] proposed a 3-D volume tracking algorithm (see also [16]). Aniszewski et al. [17] made a comparative study among different VOF methodologies. Numerous follow-up studies have addressed the problem under various impact conditions [18, 19, 20], different fluids [21], elevated wall temperatures [22], impact on non-flat [23, 24] or complex [25, 6] surfaces and impact of stream of droplets [26, 27]. Apart from the VOF method, the Piecewise linear Interface Calculation (PLIC) approach [28, 29], the Weighted Linear Interface Calculation (WLIC) method, which was introduced by Yokoi [30] and independently by Marek et al. [31] and the Tangent of Hyperbola for Interface Capturing (THINC) interface reconstruction scheme, which was described by [32]; the more recent works of [33, 34] are an extension of THINC scheme.

Fukai et al. [7] developed a finite element model (FEM) for the incompressible flow equations but the hyperbolic character of the equations was obtained by the artificial compressibility method. Although the VOF method was originally developed and has been mainly used for incompressible flows, it has been also extended to compressible fluids, see for example [33, 35, 36, 37, 38, 39]. Nowadays, VOF methods with arbitrary unstructured meshes have become popular and have been implemented in the open source CFD toolbox OpenFOAM [40, 41]. Along these lines, Gerris, an open source incompressible VOF solver with adaptive mesh refinement capabilities, originally developed by Popinet [42], has been used for two-phase flows where surface tension is prevalent but without modelling phase-change phenomena (see also [43]). Overall, such methods are in principle applicable to cases with cavitation developing during the droplet impact; however, as it is demonstrated later, accurate modelling of the liquid-gas interface becomes important at time scales much longer than the cavitation formation and collapse, and thus these methods are less important or can be even not accounted for such problems.
2.2. Models for cavitation and interaction with surfaces

As the physics and relevant models for cavitation are the primary focus of the present work, an extended summary of models is provided. The review considers models applicable both to microscales (single bubble collapses) or cavitation clouds comprising a large population of bubbles and thus more suitable for problems of engineering interest. The thermodynamic closure of such models is also briefly addressed.

2.2.1. Models suitable for single-bubbles (microscales)

From a historical perspective, interaction of cavitation bubble collapse with a nearby solid surface has been studied since 1970 [44] (see also the experimental works of Launterborn et al. [45, 46, 47]). Along similar lines are the investigations of [48, 49] on bubble deformation and collapse near a wall, employing the Boundary Element Method (BEM). This method is still being used for high fidelity bubble simulations [50] and interactions with deformable bodies [51, 52]. Despite its relative simplicity and accuracy, BEM is susceptible to instabilities and it is difficult to handle topological changes of the bubble interface [53], which require regularization and smoothing. Moreover, the potential solver, at the core of BEM, lacks small scale dissipative mechanisms leading to singularities [54]. Extensions of BEM involve Euler/Navier-Stokes flow solvers, which may include compressibility effects as well and sharp interface/ interface capturing/tracking techniques [55]. More recent work employs multiphase flow techniques for handling of the gas/liquid interface [56, 57] using a Homogeneous Equilibrium Model. Apart from single fluid approaches, various interface tracking methodologies have been employed for the prediction of pressure due to bubble collapse. A notable example of high-end simulations of bubble cloud collapse is [58]; the authors performed simulation of a resolved bubble cloud, consisting of 15,000 bubbles in the vicinity of a wall, using a supercomputer. Representative studies using the Volume Of Fluid (VOF) approach to predict bubble collapses and jetting phenomena include [59, 60, 61]. Instead of VOF, other authors [62, 63] used the Level Set (LS) technique for analyzing the effect...
of different bubbles at different distances from nearby walls. Both techniques have their advantages and disadvantages; VOF ensures conservation, whereas LS offers high accuracy calculation of the interface curvature and surface tension. An alternative to interface tracking methodologies is the front tracking method \[54\], such as the one used in \[64\] for the simulation of gas bubbles collapsing in finite/infinite liquid domains. This method differs from VOF or LS, in the sense that the interface is explicitly tracked by a set of Lagrangian marker points that define the interface topology, enabling high fidelity simulations and predictions to be made, without smearing of the interface. Assessing current methodologies, the treatment of the vapour/gas and liquid mixture, both Homogeneous Equilibrium \[57\] or non-equilibrium interface tracking immiscible fluid methodologies are applicable. While both methodologies have been successfully employed for studying the pressure field generated on the wall due to the collapse of nearby bubbles for various configurations, the methodology of interface capturing is definitely less restricting, allowing one to simulate gaseous/vaporous mixtures within the bubble, while also prescribing finite rate of mass transfer and giving the opportunity of imposing surface tension, which is important in the case of bubble nucleation. The front tracking method has the advantage of being capable of incorporating the capabilities of the interface tracking and the two fluid approach, without interface diffusion; however, it is somewhat problematic in complicated interface topologies \[65\]. With regards to simultaneous simulations of pressures resulting from the collapse of cavitating bubbles and material response to induced load, very few studies have been published \[66, 67, 68\].

2.2.2. Cavitation models suitable for engineering scales

Cavitation models applied to length/time scales of practical or engineering interest, can be classified into three categories. The first approach invokes the thermodynamic equilibrium assumption, leading to an effective mixture equation of state that returns the vapour volume fraction directly from the cell-averaged fluid state \[56\]. As this mixture model constitutes a natural sub-grid scale model for the thermodynamic fluid state, recovering the limit of individ-
ual bubbles for sufficient resolution, it can be employed within a physically motivated implicit LES approach [69]. Whereas all practical applications in engineering relevant cases at high ambient pressures indicate that the equilibrium model gives the correct prediction in terms of cavitation and wave dynamics, detailed investigations of incipient cavitation or wall-bubble interactions may depend on other processes, for example, gas content, wall crevices and local heating effects. For such phenomena at single bubbles, interfacial effects are potentially important and can be treated by sharp-interface methods [70, 56].

The second approach is based on the introduction of a rate equation for the generation of vapour that employs explicit source/sink terms. Both Eulerian-Eulerian and Eulerian-Lagrangian formulations can be used to track the vapour production and its interaction with the liquid. For example, Eulerian-Eulerian models use a bubble-cloud model applied to Reynolds-averaged turbulence modelling [71, 72] and LES. In the model of [73] instead of treating cavitation as a single mixture, the two-fluid method was employed; two sets of conservation equations are solved, one for the liquid and one for the vapour phase. With this approach the two phases can have different velocities. Another variant of the bubble model is the approach of [74] in which the classical interface capturing Volume of Fluid (VOF) method was utilised for simulating the scalar volume fraction of a bubble cloud. Similar models are currently available in commercial CFD models [76, 77, 78]. Typically, these models utilize the asymptotic form of the Rayleigh-Plesset equation of bubble dynamics. They all require information on the bubble number density and population present in the liquid prior to the onset of cavitation, while, depending on their complexity and sophistication, they may include or ignore mass transfer between the liquid and the vapour phases and may consider or not gas content in the liquid. It is clear that at their current state such models require case-by-case tuning of the involved parameters in order to predict realistic cavitation images.

The Eulerian-Lagrangian formulation also aims to provide a coupling between the interaction between the liquid (Eulerian) and vapour (Lagrangian) states. One of the most important models in this category is the Lagrangian
cavitation model of [79, 80] that uses the Rayleigh-Plesset equation of bubble
dynamics for estimating the cavitation volume fraction. More recent advances
(selectively [81, 82, 83]) have proposed models that account for collective com-
pressibility and shock wave interaction effects in polydispersed cavitating flows.
Some models do exist for predicting the collapse process of individual vapour/air
bubbles or bubble clouds within the bulk of the liquid or even near a wall sur-
face (selectively [84, 85, 86, 87]) but most of them have not been applied to
flows of industrial interest while effects such as chemical composition change,
heat transfer and liquid heating are ignored. It is also worth mentioning that
effects of dissolved gas, multi-component fluids (such as fuels) and pre-existing
nucleation sites in the fluid have not been investigated so far.

The third approach for describing cavitation effects is by employing Prob-
ability Density Functions (PDF) and related transport models. In [88] a PDF
transport model is used for the vapour fraction, based on the Boltzmann trans-
port equation, in order to model the highly dynamic and stochastic interaction
of the turbulent flow field with the cavitation structures. An additional novelty
of [88] is the fact that the solution of the PDF is done entirely in an Eule-
rian framework, avoiding the expensive cost and the inaccuracies induced by
coupling an Eulerian and Lagrangian solver. The authors have shown that by
coupling the PDF method with a compressible LES framework, they obtained
good results for a variety of Venturi-like tubes and shapes. The applicability
of such models to engineering-scale problems has not been tested yet. Finally,
apart from the aforementioned models, which are based on the finite volume
framework, there have been efforts for describing cavitation using alternative
frameworks. Examples of such works may include (a) simulation of cavities
due to the entry of high speed objects, using the mesh-less Smoothed Particle
Hydrodynamics (SPH) [89] and the Finite Element method (FEM) [90], (b)
simulation of cavities at the wake of submerged bodies in liquid [91], using
Distributed Particle Methods and focusing on the SPH method in particular,
(c) simulations of forward step geometries, resembling the orifice of injectors,
using Lattice Boltzmann methodologies [92]. These examples are, of course,
non-exhaustive. There are many different approaches, most of them at an infancy stage, for attacking the phenomenon of cavitation, each having specific advantages and disadvantages on specific flow types. On the other hand, the Finite Volume framework is mature enough and offers better handling of the underlying flow phenomena with less uncertainties over the physics for general flow types.

2.2.3. Thermodynamic closure

A common issue that is found in bubble dynamics simulations in the recent literature is the EoS of the materials involved and, more generally, material properties and their variation in respect to pressure and temperature. It is well known that gas/vapour bubbles may be at sub-atmospheric conditions when at maximum size, but during the last stages of the collapse pressures may reach the order of GPa and temperatures the magnitude of several thousand Kelvin. In the literature, however, it is commonly assumed that liquids behave according to the stiffened gas EoS and the gas/vapour as an ideal gas [58, 93, 94] despite the strong evidence that the stiffened gas EoS may not be adequate, since it cannot replicate at the same time both the correct density and the speed of sound of the liquid [95]. For this reason, many researchers have recently turned towards more accurate relationships for describing the materials involved [57] and [96] developed by the authors. Such accurate EoS have been formulated by NASA [97, 98] or in other investigations [99].

The value of the calculated pressures on the wall can be indicative of the loading expected. However, these are subject to grid resolution, as mentioned earlier. Moreover, erosion is observed after long operation time, which is something that is not addressed here.

2.3. Droplet impact and compressibility effects

The aforementioned studies regarding cavitation have never been applied so far to cases of droplet impact. There are some studies addressing compressibility effects but they have been considered only in a small part of the relevant liter-
nature. The analytic solutions of Heymann [100] and Lesser [101] were the first to consider compressibility. Heymann [100] performed a quasi-steady state 2-D analysis of the dynamics of impact between a compressible liquid droplet and a rigid surface. However, this analysis is only valid for the initial stages of the impact, during which the shock is attached to the solid surface, so the jetting in the contact edge could not be predicted. Later on, Lesser [101] expanded this work and took into account the elasticity of the surface while he also gave an analytic solution of the 3-D droplet impact problem (see also [6]). Numerical simulations have been also employed. For example, a front tracking solution procedure was proposed by Haller et al. [102] for high-speed impact of small size droplets. A rectangular finite difference Eulerian grid and a moving lower dimension Lagrangian one to track the location of the wave fronts have been utilized (see also [103]). In another compressible approach, Sanada et al. [104] used the multicomponent Euler equations to model high-speed droplet impact. They developed a third-order WENO scheme with an HLLC Riemann solver and the time advancement was achieved by a third-order TVD Runge-Kutta. More recently, Niu and Wang [105] developed a compressible two-fluid model for the Euler equations and they proposed an approximated linearized Riemann solver for the liquid-gas interface. Surface tension was neglected due to high We number, as well as in the above high-speed droplet impacts. Furthermore, they showed that higher impact speed results in higher impact pressure and possible damage in the solid surface. Algorithms able to handle liquid-gas interface have been also developed by Lacaze et al. [106], Örley et al. [107] and Gnanaskandan and Mahesh [108] but droplet impacts have not been simulated so far. More recently, Shukla et al. [35] solved the multi-component compressible flow equations with an interface compression technique aiming to capture the thickness of the interface within a few cells. Summarising, it can be said that although vast number of studies are available for compressible flows, these have not been applied so far to cases of droplet impact at conditions inducing cavitation within its volume.
2.4. The present contribution

With the exception of the observations of Field et al. [12], to the author's best knowledge, there is no other experiment and no numerical study published in which the formation and development and cavitation within the bulk of the impacting droplet is considered; the only relevant numerical study is the work of Niu et al. [105], where cavitation zones have been identified but without actually simulating the phase-change process. The aforementioned experimental data of Field et al. [12] have not been so far simulated by any of the studies available in the open literature.

This problem is addressed here for the first time using a newly developed numerical algorithm implemented in OpenFOAM. For modelling cavitation, the thermodynamic closure is achieved by a barotropic approach for the three phases [107]. In order to keep the conservative form of the solved equations, the gas phase is modelled by a VOF-like method. Moreover, a hybrid numerical flux, which is free of numerical dispersion in the phase boundaries and suitable for a wide range of Mach number flows, is also proposed. The numerical model is utilised to demonstrate and quantify the effect of pressure-driven phase change taking within the drop's volume during the initial stages of impact. The pressures induced on the solid wall during the collapse of cavitation are computed as function of the impact conditions and are compared to those resulting from the impact itself. Moreover, the influence they have of the temporal development of the splashing liquid during the initial stages of impact are explained.

The paper is organized as follows. In the following section, the numerical method is described, including the EoS for the three phases and the time/space discretization employed. Then the results are presented and discussed; verification and validation of the numerical method is performed against the the exact Riemann problem and the 2-D drop impact experiment [12], respectively. Then a parametric study utilising 2-D axisymmetric drop impacts is performed for different impact velocities; the most important conclusions are summarised at the end. Finally, in Appendix A, the methodology for deriving the exact solution to the Riemann problem for the multi-material Euler equations is discussed; this
methodology was used to obtain the exact solution for the benchmark Riemann problem. In Appendix B, the temperature difference in an isentropic compression process is calculated, justifying that way the choice of the barotropic EoS.

3. Numerical Method

In this section, the developed numerical methodology (2phaseFoam), able to predict liquid, vapour and gaseous phases co-existence under equilibrium conditions has been developed in OpenFOAM [109]; this has been based on the single-phase solver rhoCentralFoam. Initially, the main assumptions adopted for the application of the model to drop impact cases inducing cavitation are justified, followed by the mathematical description of the model itself.

3.1. Model assumptions

For the cases of drop impact investigated here, the flow can be considered inertia driven since the Reynolds number $Re$ is $10^6$; typically this is calculated for impact velocity $110\, m/s$, $D = 10\, mm$, $\rho_l = 998.207\, kg/m^3$ and thus, the viscous effects can be neglected. Moreover, interest is focused primarily during the initial stages of impact when cavitation formation and its subsequent collapse take place; these occur during the early stages of splashing which is also inertia driven, so the solution of the Euler equations instead of the full Navier-Stokes are rendered suitable for capturing the relevant physics. Furthermore, the minimum Weber number $We$ in the present drop impact simulations is calculated to be around $10^5$ and thus, surface tension is negligible; the minimum Froude number $Fr$ is 88 and therefore the gravitational forces are insignificant compared to inertia. Due to the high impact velocities which result in high We and therefore neglecting the surface tension, contact angle boundary conditions are not explicitly defined. Zero gradient boundary condition in the transport equation for the gas mass fraction is used at the wall instead (equivalent to a contact angle of $180^\circ$). Surface wettability plays an important role only when a low velocity field is noticed in the lamella and therefore adhesion forces become
significant. However, in the present study the lamella velocity is approximately 10 times higher than the \( u_{imp} = 110 \text{ m/s} \) and therefore such effects are ignored.

In the HEM approach which is followed in the present work, infinite nucleation points and infinite mass transfer rate are assumed, so thermodynamic equilibrium is achieved instantaneously. In order to add nucleation sites in the Eulerian framework, a mass transfer model is necessary, such as the Singhal model \([75]\), the Zwart-Gerber-Belamri Model \([110]\) or similar. However, such models are empirical and case dependent and thus, tuning is necessary. Alternatively, an Eulerian approach for the liquid and a Lagrangian method for the discrete bubbles based on the modified Rayleigh-Plesset equation has been employed in \([111, 112, 113]\). Apart from having a restricted validity for spherical bubbles, which is a strong assumption, such models significantly increase the computational cost. All things considered, the Eulerian diffuse interface approach, which is not possible to capture discrete nucleation sites has been utilized here as a compromise between model complexity and numerical efficiency and due to lack of information for the composition and the character of the nuclei \([114]\). This methodology has been demonstrated to accurately predict the Rayleigh collapse of vaporous structures (see \([107, 115, 116]\)). Given the original configuration and the final simulation time, which corresponds to the early stages of drop splashing, sharp interface algorithms have not been used in the present study. The drop is initially placed next to the wall impinging with velocity \( u_{imp} \) into stagnant air and as a consequence, there is no drop motion in the air before the impact. The latter would necessitate sharp interface schemes in order to avoid having a diffusive interface while the drop is travelling in the air. In addition, at later stages of splashing, which are not simulated in the present study, sharp interface algorithms are necessary in order to provide a smear-free interface. Finally, temperature effects are not taken into account in the present study, since they are negligible. The interested reader is addressed to Appendix B, where this assumption is justified.
3.2. Governing equations

The three dimensional compressible Euler equations in conservative form are considered:

\[
\frac{\partial \mathbf{U}}{\partial t} + \frac{\partial \mathbf{F}_k(U)}{\partial x_k} = 0, \quad \text{in } \Omega, \tag{1}
\]

where \( k = 1, 2, 3 \) denotes the \( x, y, z \) directions. The following initial and boundary conditions are used for the PDE system:

\[
\mathbf{U}(x, 0) = \mathbf{U}_0(x), \quad \text{in } \Omega, \tag{2}
\]

\[
\mathbf{U} = \mathbf{U}_D, \quad \text{on } \partial\Omega_D, \tag{3}
\]

\[
\frac{\partial \mathbf{U}}{\partial n} = \mathbf{U}_N, \quad \text{on } \partial\Omega_N, \tag{4}
\]

where

\[
\mathbf{U} = \begin{bmatrix} \rho & \rho Y_g & \rho u_1 & \rho u_2 & \rho u_3 \end{bmatrix}^T
\]
is the conservative solution vector, \( \rho \) is the mixture density, \( \rho Y_g \) is the gas mass fraction and \( \rho \mathbf{u} \) is the mixture momentum. Here the absence of the energy equation is due to the barotropic approach (see section 3.3), whereas a transport equation for modelling the non-condensable gas phase is used. The flux tensor \( \mathbf{F} \) is the convective term and can be analysed into \( x, y \) and \( z \) components:

\[
\mathbf{F} = \begin{bmatrix} \mathbf{F}_1 & \mathbf{F}_2 & \mathbf{F}_3 \end{bmatrix}, \text{ where:}
\]

\[
\mathbf{F}_1 = \begin{bmatrix} \rho u_1 \\ \rho Y_g u_1 \\ \rho u_1^2 + p \\ \rho u_1 u_2 \\ \rho u_1 u_3 \end{bmatrix}, \quad \mathbf{F}_2 = \begin{bmatrix} \rho u_2 \\ \rho Y_g u_2 \\ \rho u_2^2 + p \\ \rho u_2 u_1 \\ \rho u_2 u_3 \end{bmatrix}, \quad \mathbf{F}_3 = \begin{bmatrix} \rho u_3 \\ \rho Y_g u_3 \\ \rho u_3^2 + p \\ \rho u_3 u_1 \\ \rho u_3 u_2 \end{bmatrix} \tag{5}
\]
3.3. Thermodynamic Model

A homogeneous-mixture approach is used for describing the liquid, liquid-vapour regime (referred as mixture from now on) and gas phases, which means that the three phases are in mechanical and thermal equilibrium. The mixture density $\rho$ is:

$$\rho = \beta_{lm} [(1 - \alpha_v)\rho_l + \alpha_v \rho_v] + \beta_g \rho_g,$$

(6)

In the above relation, the subscripts $l, m, g$ represent the liquid, mixture and gas regimes respectively, whereas $lm$ refers to the liquid-vapour mixture which is governed by a single EoS and it is treated as a single fluid. The volume fraction is denoted by $\beta$ and $\alpha$ is the local volume fraction. The density of the component $i = l, m, g$ can be found from:

$$\rho_i = \frac{m_i}{V_i} = \frac{Y_i m}{\beta_i V} = \frac{Y_i \beta_i V}{\rho},$$

(7)

where the volume fraction $\beta$ of the $i$ component is:

$$\beta_i = \frac{V_i}{V}, \quad \sum_i \beta_i = 1,$$

(8)

the mass fraction $Y_i$ of the $i$ component is:

$$Y_i = \frac{m_i}{m}, \quad \sum_i Y_i = 1,$$

(9)

and the local volume fraction can be calculated from the formula:

$$\alpha_v = \begin{cases} 0, & \rho \geq \rho_{i,sat} \\ \frac{\beta_{lm} \rho_{i,sat} - \rho_{i,m}}{\rho_{i,sat} - \rho_{i,v,sat}}, & \rho < \rho_{i,sat} \end{cases}$$

(10)

The single fluid model for the liquid and mixture is extended by a transport equation for the non-condensable gas. A linear barotropic model has been utilized for the pure liquid and mixture ($lm$). The density $\rho_{lm}$ of the latter is:

$$\rho_{lm} = \rho_{i,sat} + \frac{1}{c^2} (p - p_{sat}), \quad c = \begin{cases} c_l, & p \geq p_{sat} \\ c_m, & p < p_{sat} \end{cases}$$

(11)
where \( \rho_{l,sat} \) is the density of the liquid at saturation condition and \( c \) is the speed of sound of the liquid or the mixture, depending on the saturation pressure \( p_{sat} \).

The gas phase, has been modelled by an isothermal ideal gas EoS and thus, the gas density is given by:

\[
\rho_g = \frac{p}{R_g T_{ref}},
\]

where the reference temperature is \( T_{ref} = 293.15 \, K \) and the specific gas constant is \( R_g = 287.06 \, J/(kg \, K) \). The barotropic approach is followed since the temperature difference in the following simulations is negligible (the interested reader is referred to Appendix B, where the temperature difference in an isentropic compression process is calculated).

Differentiating isentropically Eq. (11) with respect to density, constant speed of sound for the liquid and mixture is found for water: \( c_l = 1482.35 \, m/s \) and \( c_m = 1 \, m/s \), following Brennen [114] and Örley et al. [107]. For the ideal gas, the speed of sound is calculated from:

\[
c_g = \sqrt{R_g T_{ref}},
\]

where the specific heat ratio \( \gamma = \frac{C_p}{C_v} \) is unity (isothermal approach). In the three phase mixture, the speed of sound between \( lm \) and \( g \) phases is determined by the Wallis speed of sound [114, 117]:

\[
\frac{1}{\rho c^2} = \frac{1}{\rho_{lm} c_{lm}^2} + \frac{\beta_g}{\rho_g c_g^2},
\]

In order to calculate the pressure of the mixture, a closed form equation of state describing the co-existence of three phases is employed from Eq. (6):

\[
\rho = \beta_{lm} \left[ \rho_{l,sat} + \frac{1}{c^2} (p - p_{sat}) \right] + \beta_g \frac{p}{R_g T_{ref}},
\]

replacing the volume fraction \( \beta_g \) from Eq. (7) and eliminating \( \beta_{lm} \) by using Eq. (9) and Eq. (12), a quadratic equation for the pressure is derived:

\[
Ap^2 + Bp + C = 0,
\]
where

\[ A = \frac{1}{c^2}, \]  

\[ B = \rho(Y_g - 1) + \rho_{l, sat} - \frac{p}{c^2} - \frac{Y_g \rho R_g T_{ref}}{c^2}, \]  

\[ C = Y_g \rho R_g T_{ref} \left( \frac{p_{sat}}{c^2} - \rho_{l, sat} \right). \]

In the case of two real solutions \( p_1, p_2 \in \mathbb{R} \), the largest root of Eq. (16) is kept. The speed of sound in Eq. (17), (18) and (19) is set to either \( c_l \) or \( c_m \), depending on the pressure at the previous time step for identifying the liquid or mixture regions. Therefore, Eq. (16) is solved iteratively, in case the computed pressure does not fulfill the original assumption. In practice, the algorithm is repeated for no more than three iterations.

3.4. Discretization

Due to the large variation in the speed of sound, the Mach number in three phase flows can range from \( 10^{-2} \) up to \( 10^2 \) or even higher [118]. As it can be seen in the previous sub-section from Eq. (13) and (11), the speed of sound can vary from \( 1 \text{ m/s} \) in the mixture regime, up to \( 1482.35 \text{ m/s} \) in the liquid region, whereas in the gaseous phase the speed of sound is \( 290 \text{ m/s} \). This is an obstacle in density-based solvers, since they are prone to slow convergence and dispersion in low Mach number flows [119, 120, 121]. In order to handle the low Mach number problem, a hybrid flux, suitable for multiphase flows, is proposed here for first time.

The aforementioned flux is based on the Primitive Variable Riemann Solver (PVRS) [122] and the Mach consistent numerical flux of Schmidt et al. [123]. That way, an efficient and robust solver is developed, by utilizing an approximated Riemann solver, instead of the exact one. At the same time, the numerical
scheme is suitable for subsonic up to supersonic flow conditions. The numerical
inviscid flux in the $k$ direction at the $i + 1/2$ interface takes the following form:

$$
\mathbf{F}^{i+1/2} = \rho^{L/R} u^* \begin{bmatrix}
1 \\
y_g^{L/R} \\
u_1^{L/R} \\
u_2^{L/R} \\
u_3^{L/R}
\end{bmatrix}
+ p^* \begin{bmatrix}
0 \\
0 \\
\delta_{1k} \\
\delta_{2k} \\
\delta_{3k}
\end{bmatrix},
$$

(20)

where the interface velocity $u^*_k$ is approximated by:

$$
u^*_k = \frac{1}{C_L + C_R} \left[ C_L u^L_k + C_R u^R_k + (p^L - p^R) \right],
$$

(21)

and $C$ is the acoustic impedance $C = \rho c$. The interface pressure $p^*$ is:

$$
p^* = (1 - \beta) p^{*,\text{incr}} + \beta p^{*,\text{comp}}.
$$

(22)

In Eq. (22), the interface pressure is the sum of the incompressible and the
compressible parts, where the incompressible contribution is:

$$
p^{*,\text{incr}} = \frac{C_L p^R + C_R p^L}{C_L + C_R},
$$

(23)

and the compressible contribution is:

$$
p^{*,\text{comp}} = \frac{C_L p^R + C_R p^L + C_R C_L (u^L_k - u^R_k)}{C_L + C_R}
$$

(24)

Depending on the Mach number, the contribution of the incompressible or the
compressible part in Eq. (22) is more dominant and the weighted term $\beta$ is :

$$
\beta = 1 - e^{-\alpha M},
$$

(25)

where the Mach number $M$ is defined as:

$$
M = \max\left( \frac{|\mathbf{u}^L|}{c^L}, \frac{|\mathbf{u}^R|}{c^R} \right).
$$

(26)
The blending coefficient is $\alpha \sim (10, 100)$. For incompressible single phase flow, Eq. (23) is taking the form of $\frac{1}{2}(p_L + p_R)$ since $C^L = C^R$. However, for two-phase flows, Eq. (23) is much closer to the exact solution.

Linear interpolation (2nd order spatial accuracy) with van Leer flux limiter has been used [124]. A four stage Runge-Kutta (RK), 4th order accurate in time has been implemented for time advancement [122], in order to capture the waves which are propagating in the domain.

4. Results

In this section, verification and validation of the numerical method is performed; then, the effect of various impact velocities on a 2-D axisymmetric drop impact is investigated. The Riemann problem is chosen for verifying the algorithm accuracy and demonstrating its ability to resolve wave dynamics. Possible difficulties of the numerical scheme, which is prone to numerical diffusion and dispersion, especially at the phase boundaries are also investigated. The 2-D planar drop impact case is then selected for qualitative validation of the propagating shock and the reflected expansion waves against available experimental data. Finally, the 2-D axisymmetric drop impingement on a solid wall is modelled for different impact velocities, in order to investigate the extent of the cavitation zone and how bubble collapse can possibly lead to material erosion. The drop impact simulations are summarised in Table 1, where the Reynolds, Weber and Froude numbers are calculated.

4.1. Riemann Problem

The first benchmark case is the Riemann problem in the computational domain $x \in [-0.5, 0.5]$ with initial conditions for the left state: $\rho_L = 998.2 \text{ kg/m}^3$, $u_L = 0 \text{ m/s}$, $Y_g = 0$ and for the right state: $\rho_R = 0.017 \text{ kg/m}^3$, $u_R = 0 \text{ m/s}$, $Y_g = 1$. Wave transmissive boundary conditions have been used for the left and the right sides of the shock tube, that is $U_{n+1}(x = L) = U_n(x = L)$ and $U_{n+1}(x = 0) = U_n(x = 0)$. A CFL number of 0.5 was chosen for the time
Table 1: Numbering, description, impact velocity, Reynolds, Weber and Froude numbers of the drop impact cases which have been simulated. As wedge are denoted the 2-D axisymmetric simulations and no air means that in the initial condition the drop is attached to the wall, in comparison to the rest of the simulations where the drop is 3 cells above the wall in the beginning of the simulation.

step selection in the explicit algorithm. Comparison between the exact and the numerical solution is shown in Fig. 1 at time $t = 0.1 \mu s$, where second order of spatial accuracy with 500 equally spaced cells in the x direction was used for obtaining the numerical solution. A close-up view in order to compare first and second order in space schemes with resolution either 500 or 1000 equally spaced cells in the x direction is shown in Fig. 2. In Fig. 1, the exact solution of the Riemann problem and the computed one are in satisfactory agreement and the wave pattern has been correctly captured. As it was expected in Fig. 2, the 2nd order solutions in space have minimal numerical diffusion, which is dominant in the 1st order schemes. In addition, the computed solution is getting closer to the exact by increasing the mesh resolution and the numerical diffusion is eliminated. No dispersion is noticed at the boundary interface (between the gas and the liquid), which is the case when using conventional schemes such as HLLC or similar. The exact solution of the Riemann problem is not trivial for multi-material cases and it has been derived following the Appendix A of the present paper.
4.2. Planar drop impact

The second test case examined is a planar 'drop' impact on a solid wall for which experimental data are available [12]. A 2-D simulation, with second order discretization in space has been performed in order to validate the algorithm against the 2-D experimental data of Field et al. [12]. In the experimental apparatus of [12], a small quantity of liquid was placed between two transparent plates, separated by a small distance. Due to surface tension, the liquid formed a circular area of diameter $D = 10 \text{ mm}$; the distance between the two plates is negligible compared to the diameter $D$. The impact was modelled by a third plate which was projected with velocity $110 \text{ m/s}$ among the two plates. In the numerical simulation, the water drop ($Y = 0$) and the surrounding air ($Y = 1$) were set as initial conditions in the transport equation for the gas mass fraction. Therefore, the centre of the drop was placed at $(x_0, y_0) = (0, 0.00505) \text{ m}$ in the computational domain $(-0.2, 0.2) \times (0, 0.2) \text{ m}$; 150 cells have been placed along the initial drop radius $R$ (grid size $\sim 33 \mu m$). The same cell size as in the drop radius has been kept until distance $2R$ in the positive and negative x-direction and until $1.5R$ in the positive y-direction. After that, a stretching ratio of 1.05 has been applied, resulting in a total amount of $380k$ cells (see the left image of Fig. 3). A CFL number of 0.5 was chosen for the time step selection ($\Delta t \sim$
Figure 2: Close-up view of the Riemann problem. Comparison of the x-velocity (left) and pressure (right) between the exact and the numerical solution at time \( t = 0.1 \mu s \). First and second order spatial accuracy schemes with resolution of 500 and 1000 cells have been used.

\[ 5 \cdot 10^{-9} \text{s} \) in the explicit algorithm. Initially, the pressure of the surrounding air and the water drop is atmospheric, \( p(t = 0) = 101326 \text{Pa} \). In this way, the initial density for the two phases is calculated from the barotropic EoS: \( \rho_l(t = 0) = 998.207 \text{kg/m}^3 \) and \( \rho_g(t = 0) = 1.204 \text{kg/m}^3 \). Zero gradient boundary conditions have been selected for the right, left and upper faces, whereas the lower face is set as wall. In Fig. 4 the experiment [12] (left) and the numerical solution (right) for the drop impact are compared.

Figure 3: Computational grids for the planer drop impact (left) and for the 2-D axisymmetric drop impact (right).
The main mechanisms noticed both in the experimental work [10, 12] and past numerical simulations [102, 104, 105] are jetting, as well as shock and expansion waves; these are also identified in the present study. In the aforementioned compressible numerical studies, cavitation was not modelled and different impact conditions were simulated compared to the present work. In frame (a) the drop impacts the wall, whereas in the next frame, a shock wave is forming, as a result of the impact. While the liquid close to the impact point is compressed, the information of the impact has not travelled in the rest of the drop, which is still moving with the impact velocity [100]. Those two regions are separated by the shock front (frame (b)), which is created by individual wavelets emanating from the contact edge [101]. In the preliminary stages of the impact, the edge velocity is higher than the speed of sound and there is a tendency to decrease. As long as the edge velocity is higher than the shock speed, the shock is attached to the contact edge. When the edge velocity reaches the critical value of the shock speed, the shock wave is detached from the contact line (frame (c)) and it is propagating in the rest of the liquid (until frame (g)). This mechanism is responsible for the expansion of the liquid and the jetting, which is created in the contact edge (frame (d), denoted as J in the experimental results). In frames (e), (f) and (g), the shock wave is reflected normal to the free surface as an expansion wave which focuses in the inner region of the drop. These low pressure areas are potential cavitation regimes and their extent, as well as the volume of the vapour depend on the impact velocity [105]. In frames (g), (h), the shock wave reaches the highest point of the drop and it is then reflected downwards. In the last frames, the jetting is more advanced and the reflected shock is shown in the upper middle of the drop at frames (i) and (j) (denoted as R in frame (i) and focused to point F in frame (j) of the experiment).

Comparing the present simulation with previous experimental studies of Field et al. [12], similar wave structures at the same time scale are noticed. The edge pressure in the contact edge is around 0.22 GPa and it exceeds the water hammer pressure [10], which is estimated about 0.16 GPa, where the water hammer pressure is defined as $p_{wh} = \rho_l c_l u_{imp}$. The shock wave moving...
upwards and its reflection have been recognized at similar time frames between the experiment and the simulation. Furthermore, the jetting (starting from frame \((d)\)) is around ten times the impact speed, or even higher, as it has been mentioned in [10]. Rarefaction waves have been also identified in the later stages of the drop impact and they follow the same pattern as in the experimental study. The production of vapour in the final stages is evident due to the pressure drop and the areas where vapour is generated are in accordance to the experiment. However, in the experimental study the maximum volume of vapour is in the centre of the drop, whereas in the present work, vapour is more dominant on the upper sides, perimetrically of the drop. This is because the bulk liquid tension cannot be captured with the present methodology.

Figure 4: Validation of the numerical solution (right) against experiment (left) for a 2-D drop impact on a solid wall with impact velocity 110 m/s. The interframe time is \(t = 1 \mu s\). The left figure is taken from Field et. al [12].
4.3. 2-D axisymmetric drop impact

The previous simulation is now performed in a 2-D axisymmetric computational domain, in order to model the impact of spherical drops. A 3-D simulation would generally capture the 3-D interfacial instabilities due to surface tension, but since the We number is above $10^5$ and in order to reduce the computational cost, a 2-D axisymmetric simulation is performed instead. The drop impact time scale is $t_{\text{impact}} = D/u_{\text{imp}}$ and in the present configuration for impact velocity $u_{\text{imp}} = 110 \text{ m/s}$ is calculated to be $t_{\text{impact}} \approx 9 \cdot 10^{-5} \text{ s}$, whereas the cavitation collapse time is approximated from the characteristic Rayleigh time $t_{\text{cav}} = 0.915 R_0, v_{\text{ap}} \sqrt{\frac{\rho_l}{p_{\infty} - p_{\text{sat}}}}$ and it is calculated to be $t_{\text{cav}} \approx 2.2 \cdot 10^{-5} \text{ s}$.

Starting from the half of the 2-D meshes of 4.2, a wedge of 5 degrees has been simulated by taking advantage of the axial symmetry (see the right image of Fig. 3). The same initial and boundary conditions are kept, apart from the wedge faces and the axis of symmetry. At the beginning, a grid independence analysis is performed and then, the effect of the impact velocity magnitude is investigated for the intermediate grid. Second order accurate spatial discretization schemes have been used for this simulation and a CFL number of 0.5 was chosen for the time step selection ($\Delta t \sim 3 \cdot 10^{-10} \text{ s}$) in the explicit algorithm.

In the following figures, pressure has been non-dimensionalized with the water hammer pressure $p_{\text{wh}}$, velocity with the impact velocity $u_{\text{imp}}$ and the dimensionless time is calculated from: $t = \frac{T - t_{\text{bimp}}}{D/c_l}$, where $t_{\text{bimp}} = 0.00005 / u_{\text{imp}}$ is the time of the impact, based on the initial configuration (in cases where the drop is not attached to the wall, but there is air between them). This way, the shock wave will be at the same y-position at a given non-dimensional time for all impact velocities.

In Fig. 5 the results of the grid independence study are shown, for an impact velocity of $110 \text{ m/s}$. Three different grids have been utilized, with 117 $k$, 380 $k$ and 1.5 $M$ cells. In the fine area: $(0, 2R) \times (0, 1.5R)$ the resolution of $330 \times 225$, $660 \times 450$ and $1320 \times 900$ cells has been used for the three different grids. On the left-hand side of Fig. 5 the maximum wall pressure with respect to time is shown and on the right-hand side the generated volume of vapour at a line
parallel to the y axis ($x = 0.6 \text{mm}$) at time $t = 1.19$ is plotted. The maximum wall pressures are similar for all grids and the peak noticed in the vapour volume fraction after $y = 0.8$ is almost identical for all resolutions. It can be concluded from the above study that there is convergence of the solution for the selected grid resolutions. The intermediate grid ($380 k$ cells), referred as case 2 from now on, is considered to be accurate enough and it is selected for the rest of the simulations.

In Fig. 6 and 7 the evolution of the drop impact is shown for case 2. More specifically, in Fig. 6 the pressure field (left half) and the velocity magnitude (right half) are shown in conjunction with the iso-surface of 0.5 gas mass fraction on the left figures; whereas on the right figures, the numerical Schlieren is depicted by utilizing different scales for the inner and the outer computational domain of the drop in order to capture the different waves, which are propagating in the liquid water and in the air. In Fig. 7 the wall pressure (lower part) and the vapour volume fraction (upper part) combined with the iso-surface of 0.5 gas mass fraction are demonstrated for case 2. The main mechanisms and the flow pattern in the 2-D axisymmetric simulation (case 2) are similar to the planar one (case 1) for the same impact velocity ($110 \text{ m/s}$). At time $t = 0.44$ the drop has already impacted the wall and the shock wave is visible in the Schlieren figure. The jetting has started, however it is more evident at time $t = 0.89$ and it is responsible for the non-spherical shape of the drop. As the shock moves to the upper half of the drop, it is reflected on the drop surface and expansion waves, which are moving downwards, are noticed in the Schlieren figures, starting from time $t = 0.89$. Those rarefaction waves create low pressure areas and thus, cavitation is noticed at times $t = 1.19$ and $t = 1.48$ (see also Fig. 7). The maximum wall pressure is realised at the moment of the impact and it decreases afterwards (see Fig. 12).

The planar and the axisymmetric solutions exhibit many similarities; nevertheless, there is a discrepancy in the pressure field between case 1 and case 2. The maximum wall pressure is higher in case 1, as it can be seen in Fig. 8 and has been also noticed in previous studies [10]. In case 1 the shock wave propa-
gates in a cylindrical pattern and it is reflected on the upper half surface of the cylinder, whereas in case 2 the shock wave travels in a spherical pattern and it is reflected on the upper surface of the spherical drop. The three-dimensionality of the latter results in a shock wave of the half pressure strength (∼10 MPa), compared to the planar case (∼20 MPa).

In Fig. 9 the above results are compared to lower impact velocities, 55 m/s and 27.5 m/s at the same dimensionless time $t = 1.48$. The same configuration as in the left image of Fig. 6 is followed here as well. The drop spreading at lower impact speeds is less dominant and the drop is closer to the spherical shape, as it can be seen from the drop iso-surface plots. On the other hand, in case 2 the transition to splashing is evident, as the jetting area is split to two different regions. Furthermore, the high pressure area and the lamella are larger in case 2 but the ratio $|u_{max}|/u_{imp}$ in all cases (case 2-4) is between 7.2 and 11, whereas the ratio $p_{max}/p_{wh}$ is around 0.13. Although the above indicate similar non-dimensional maximum pressures and jetting velocities regardless the impact velocity, it is worth pointing out that the maximum pressure and velocity fields are significantly lower in case 3 and 4. For example, the jetting velocity is reduced by even one order of magnitude (∼1400 m/s in case 2 and ∼190 m/s in case 4).

In order to compare the vapour generated for each impact velocity at the same non dimensional time $t = 1.48$, slices with the vapour volume contour (upper) combined with the same iso-surface are shown in Fig. 10 for case 2, 3 and 4. For the highest impact velocity (case 2) the vapour volume is increased even one order of magnitude compared to the values of lower velocities. It can be concluded that the amount of the vapour and the extent of the cavitation area, which is generated at later stages, monotonically depends on the impact velocity (this is also evident in Fig. 12 where 6 different impact velocities are examined). The wall pressure (bottom) is also depicted in Fig. 10 although the maximum is approximately the same for all cases, it extends to a larger area for higher impact velocities.

At a later stage of the drop impact (Fig. 11), the splashing is more evident.
than at time $t = 1.48$. In Fig. 11 the pressure field (left slice) and the velocity magnitude (right slice) are shown in conjunction with the iso-surface of 0.5 gas mass fraction on the left figures, whereas on the right figures the wall pressure (lower slice) and the vapour volume fraction (upper slice) combined with the iso-surface of 0.5 gas mass fraction are demonstrated for case 2. Several vaporous regions have been created from the rarefaction waves and they start collapsing consecutively. At times $t = 3.19$ and $t = 3.56$ the third and second vaporous regions have just collapsed respectively. A peak in the pressure due to the shock wave created by the collapse is noticed at times $t = 3.56$ and $t = 3.64$, however the location (far away from the wall) and the strength (maximum pressure is 0.09$p_{wh}$) cannot denote erosion.

In Fig. 12 a parametric study for six different impact velocities (case 2-7) is performed for the intermediate grid resolution, where the maximum wall pressure (left) and the generated volume of vapour (right) with respect to time are plotted. As it has been already discussed in the previous paragraph and in previous studies [7, 105], it is straightforward that higher impact velocities result in higher wall pressures (although the ratio $\frac{p_{\text{max,wall}}}{p_{wh}}$ is almost constant regardless of the impact velocity). More production of vapour due to the reflection of a stronger shock developing during the liquid-solid contact is calculated. The cavitation inside the drop may also contribute to pressure increase on the solid surface at the bubble collapse stage. This is shown on the wall pressure figure, where at higher impact velocities there are small peaks occurring at later times (case 7).

It is remarkable that the initial configuration can affect the existence or not of cavitation and material erosion close to the wall, even for low impact velocities. As initial condition in case 8 is now selected the drop to be attached to the wall (in contrast to case 1-7), so there is no air between them. To demonstrate that the impact velocity is not the determining factor here, $u_{imp} = 27.5 \text{ m/s}$ was selected. Surprisingly enough, in Fig. 13 vapour is created at the impact point and a vaporous region is formed above it due to a rarefaction wave at an early stage of the impact. The maximum vapour volume fraction created is even three
times higher than case 2 at time $t = 1.48$, where the impact velocity is four
times larger. Consequently, there is a significant increase in the pressure field
due to the collapse, as it can be observed in Fig. 14 which results in around
60% higher wall pressure, compared to case 3. In practice, the above case can
be realised at steam turbine blades, where the rarefied environment implies very
low steam density, consequently there is little drop/vapour interaction.

5. Conclusions

In the present work, the impact of drops onto solid surfaces at conditions
inducing cavitation within its volume have been addressed. Initially, a litera-
ture review on the subject has been given, focusing primarily on computational
studies. It is apparent that the vast majority of them assume incompressible
liquids and aim to resolve the temporal development of the drop/gas interface.
Studies that consider the heat transfer and phase-change phenomena induced
during impact at elevated wall temperature as well as wettability effects have
not been addressed here. However, more relevant to the present study are the conditions at high impact velocities where liquid compressibility becomes important. For conditions inducing cavitation within the drop’s volume, only one set of experiments is reported in the literature while no computational study has been performed so far. Aiming to provide further insight into this problem, an explicit density-based solver of the Euler equations, able to model the co-existence of non-condensable gases, liquid and vapour phases has been developed and implemented in OpenFOAM. Moreover, a Mach number consistent numerical flux, capable of handling a wide range of Mach number flows and producing smooth solutions at the phase boundaries has been proposed. The main model assumptions and simplifications have been justified for the flow conditions of interest to the present study. The developed algorithm was then validated against the Riemann problem, followed by the comparison against the 2-D planar ‘drop’ impact experiment, showing satisfactory agreement, as similar flow patterns have been identified. Following, simulation of the impact of spherical drops on a solid surface have been performed, including for the first time the simulation of cavitation formation and collapse. These cavitation regimes are formed by the reflection of the shock wave on the outer surface of the drop as an expansion wave.

The drop impact time scale is $t_{\text{impact}} = D/u_{\text{imp}}$ and in the present configuration for impact velocity $u_{\text{imp}} = 110 \text{ m/s}$ is calculated to be $t_{\text{impact}} \approx 9 \cdot 10^{-5} \text{ s}$, whereas the cavitation collapse time is approximated from the characteristic Rayleigh time $t_{\text{cav}} = 0.915 R_0 \sqrt{\frac{\rho_l}{\rho_{\infty} - p_{\text{sat}}}}$ and it is calculated to be $t_{\text{cav}} \approx 2.2 \cdot 10^{-5} \text{ s}$. The significantly larger time scale ($t_{\text{impact}} \approx 9 \cdot 10^{-5} \text{ s}$) of the drop impact phenomenon in comparison to the characteristic time of the cavitation collapse ($t_{\text{cav}} \approx 2.2 \cdot 10^{-5} \text{ s}$) justifies why the collapse of the vaporous regions inside the drop don’t affect the shape of the drop and its splashing. Increased impact velocity may result in more damage and possibly material erosion not only because of higher impact pressure, but also due to the collapse of the vaporous bubbles inside the drop. It is found that the initial location of the drop with respect to the solid surface, which actually means the absence or not of...
gas around the drop, can influence the volume of cavitation generated at the initial stages of the impact. If there is no gas between the drop and the solid surface, pressure can get close to its maximum value, which is at the moment of the impact \( p_{wh} \) and material erosion may take place \( p_{wh} = 160 \text{ MPa} \) for \( u_{imp} = 110 \text{ m/s} \) and the yield strength of steel is \( 200 - 300 \text{ MPa} \). It should be clarified here that the above phenomenon can even occur at low impact velocities, for instance at impact velocity \( u_{imp} = 27.5 \text{ m/s} \).

Appendix A. Exact Riemann problem for multi-material problems

In this section, the methodology for finding the exact solution to the Riemann problem for the multi-material Euler equations is derived. In the literature there are limited works discussing exact Riemann solvers for multi-material applications. Mainly, these focus on multiple velocities, pressures and temperature fields, see e.g. [125, 126]. The discussion here will be limited to just two different materials sharing the same velocity, pressure and temperature fields. The materials will be referred to as material-1 and material-2, however the methodology may be extended to any number of materials. For the sake of generality, the discussion will not be limited to an explicit form of equation of state. Instead, the equations of state for the two distinct materials will be assumed to depend on density and internal energy only, i.e. have a form \( p = p(\rho) \) or \( p = p(\rho, e) \), which may have an explicit formula or be in tabular form as in [127, 96]. Material variation will be tracked using a mass fraction transport equation which
will affect the mixture equation of state. Thus, the mixture equation of state that will be examined is of the form \( p = p(\rho, Y) \) or \( p = p(\rho, e, Y) \), where \( Y \) is the mass fraction of material-2, defined in Eq. \( (9) \). Following Toro \[122\], the form of the Riemann problem solved is:

\[
\begin{aligned}
\frac{\partial \mathbf{U}}{\partial t} + \frac{\partial \mathbf{F}(\mathbf{U})}{\partial x} &= 0 \\
\mathbf{U}(x, 0) &= \begin{cases} 
\mathbf{U}_L, & x < 0 \\
\mathbf{U}_R, & x \geq 0 
\end{cases}
\end{aligned}
\quad (A.1)
\]

The same nomenclature as in the rest of the paper is used.

**Appendix A.1. Pressure is only a function of density and mass fraction**

In case the mixture pressure is only a function of density and mass fraction, \( p = p(\rho, Y) \) the conservative variables and the flux vector are:

\[
\mathbf{U} = \begin{bmatrix} \rho \\ \rho u \\ \rho Y \end{bmatrix}, \quad \mathbf{F}(\mathbf{U}) = \begin{bmatrix} \rho u \\ \rho u^2 + p \\ \rho u Y \end{bmatrix}, \quad (A.2)
\]

To derive the Jacobian matrix, it is convenient to recast the \( \mathbf{U} \) and \( \mathbf{F}(\mathbf{U}) \) vectors and equation of state \( p = p(\rho, Y) \), as:

\[
\mathbf{U} = \begin{bmatrix} u_1 \\ u_2 \\ u_3 \end{bmatrix}, \quad \mathbf{F}(\mathbf{U}) = \begin{bmatrix} u_2 \\ \frac{u_2^2}{u_1} + p\left(\frac{u_1}{u_1}, \frac{u_3}{u_1}\right) \\ \frac{u_3}{u_1} \end{bmatrix}, \quad (A.3)
\]

\[ p = p\left(\frac{u_1}{u_1}, \frac{u_3}{u_1}\right) \quad (A.4) \]
The Jacobian matrix is calculated as:

\[
A(U) = \begin{bmatrix}
\frac{\partial f_1}{\partial u_1} & \frac{\partial f_1}{\partial u_2} & \frac{\partial f_1}{\partial u_3} \\
\frac{\partial f_2}{\partial u_1} & \frac{\partial f_2}{\partial u_2} & \frac{\partial f_2}{\partial u_3} \\
\frac{\partial f_3}{\partial u_1} & \frac{\partial f_3}{\partial u_2} & \frac{\partial f_3}{\partial u_3}
\end{bmatrix}
\] (A.5)

After calculating all terms and replacing back the conservative variables:

\[
A(U) = \begin{bmatrix}
0 & 1 & 0 \\
\frac{\partial p}{\partial \rho} - u^2 - \frac{\partial p}{\partial Y} Y \rho & 2u & \frac{1}{\rho} \frac{\partial p}{\partial Y} \\
-uY & Y & u
\end{bmatrix}
\] (A.6)

The eigenvalue analysis of the Jacobian matrix results to:

\[
\lambda_1 = u - c \\
\lambda_2 = u \\
\lambda_3 = u + c
\] (A.7)

and right eigenvectors:

\[
K_1 = \begin{bmatrix} 1 \\ u - c \\ Y \end{bmatrix}, \quad K_2 = \begin{bmatrix} \frac{\partial p}{\partial Y} \\ u \frac{\partial p}{\partial Y} \\ Y \frac{\partial p}{\partial Y} - \rho \frac{\partial p}{\partial \rho} \end{bmatrix}, \quad K_3 = \begin{bmatrix} 1 \\ u + c \\ Y \end{bmatrix}
\] (A.8)

where \(c\) is the speed of sound equal to \(\sqrt{\frac{\partial p}{\partial \rho}}\). The waves associated with \(\lambda_1, \lambda_3\) eigenvalues are non-linear waves (shock waves or rarefaction waves) and the \(\lambda_2\) eigenvalue is a linearly degenerate wave associated with a contact discontinuity.
Appendix A.2. Pressure is a function of density, internal energy and mass fraction

In case the mixture pressure is only a function of density, internal energy and mass fraction, $p = p(\rho, e, Y)$ the conservative variables and the flux vector are:

$$
\begin{align*}
U &= \begin{bmatrix}
\rho \\
\rho u \\
\rho E \\
\rho Y
\end{bmatrix}, \\
F(U) &= \begin{bmatrix}
\rho u \\
\rho u^2 + p \\
u(\rho E + p) \\
\rho u Y
\end{bmatrix}, \\
\text{(A.9)}
\end{align*}
$$

where $E = \frac{1}{2}u^2 + e$, with $e$ the internal energy. To derive the Jacobian matrix, it is convenient to recast the $U$ and $F(U)$ vectors and EoS $p = p(\rho, e, Y)$ as:

$$
\begin{align*}
U &= \begin{bmatrix}
u_1 \\
u_2 \\
u_3 \\
u_4
\end{bmatrix}, \\
F(U) &= \begin{bmatrix}
u_2 \\
\frac{u^2_2}{u_1} + p\left(u_1, \frac{u_3}{u_1} - \frac{u_2^2}{2u_1}, \frac{u_4}{u_1}\right) \\
\frac{u_2}{u_1}\left(u_3 + p\left(u_1, \frac{u_3}{u_1} - \frac{u_2^2}{2u_1}, \frac{u_4}{u_1}\right)\right) \\
\frac{u_4u_2}{u_1}\end{bmatrix}, \\
\text{(A.10)}
\end{align*}
$$

$$
p = p\left(u_1, \frac{u_3}{u_1} - \frac{u_2^2}{2u_1}, \frac{u_4}{u_1}\right) \\
\text{(A.11)}
$$

The Jacobian matrix is:
\[ A(U) = \begin{bmatrix}
0 \\
\frac{2 \partial p}{\partial \rho} u + \frac{\partial p}{\partial \rho} (u^2 - 2e) - 2 \left( \rho u^2 + \frac{\partial p}{\partial Y} Y \right) \\
\frac{2p}{u} \left( - \frac{\partial p}{\partial \rho} u^2 + \rho u^2 + 2 \frac{\partial p}{\partial \rho} e - 2p \frac{\partial p}{\partial \rho} + 2 \rho \frac{\partial p}{\partial \rho} + 2 \rho \frac{\partial p}{\partial \rho} + 2 \rho \frac{\partial p}{\partial \rho} \right) \\
\frac{2p}{u} \left( - \frac{\partial p}{\partial \rho} u^2 + \rho u^2 + 2 \frac{\partial p}{\partial \rho} e - 2p \frac{\partial p}{\partial \rho} + 2 \rho \frac{\partial p}{\partial \rho} + 2 \rho \frac{\partial p}{\partial \rho} + 2 \rho \frac{\partial p}{\partial \rho} \right) \\
-1 \\
\frac{\left( 2 - \frac{\partial p}{\partial \rho} \right)}{2p} u + \frac{\partial p}{\partial \rho} \frac{1}{\rho} + \frac{\partial p}{\partial \rho} \frac{1}{\rho} \\
\frac{\left( \rho - 2 \frac{\partial p}{\partial \rho} \right)}{2p} u^2 + 2p + 2e \rho \\
\frac{1}{\rho} u \left( \frac{\partial p}{\partial \rho} + \rho \right) + \frac{\partial p}{\partial \rho} \frac{1}{\rho} \\
0 \\
Y \\
0 \\
u
\end{bmatrix} \quad (A.12) \]

The Jacobian eigenvalues \([\lambda_1, \lambda_2, \lambda_3, \lambda_4]\) are:

\[ \lambda_1 = u - c \]
\[ \lambda_2 = \lambda_3 = u \]
\[ \lambda_4 = u + c \]  

(A.13)
and right eigenvectors:

\[
K_1 = \begin{bmatrix}
1 \\
\frac{1}{2}(u^2 - cu + 2p/\rho + 2e) \\
y
\end{bmatrix}, \quad
K_2 = \begin{bmatrix}
2 \frac{1}{X} \frac{\partial p}{\partial Y} \\
2 u \frac{\partial p}{\partial Y} \\
1
\end{bmatrix},
\]

\[
K_3 = \begin{bmatrix}
2 \frac{1}{X} \frac{\partial p}{\partial e} \\
2 u \frac{\partial p}{\partial e} \\
1
\end{bmatrix}, \quad
K_4 = \begin{bmatrix}
1 \\
u + c \\
\frac{1}{2}(u^2 + cu + 2p/\rho + 2e) \\
y
\end{bmatrix},
\]

where \( c \) is the speed of sound, defined as: \( c = \sqrt{\frac{\partial p}{\partial \rho} + \frac{\partial p}{\partial e} \frac{\rho}{\rho}} \) and \( X = \frac{\partial p}{\partial e} u^2 + 2 \frac{\partial p}{\partial e} - 2 \frac{\partial p}{\partial \rho} \rho + 2 \frac{\partial p}{\partial Y} Y \).

The waves associated with \( \lambda_1, \lambda_4 \) eigenvalues are non-linear waves (shock waves or rarefaction waves) and the \( \lambda_2, \lambda_3 \) eigenvalues are linearly degenerate waves associated with a contact discontinuity.

Appendix A.3. Exact solver derivation

Despite the difference in the Jacobian matrix structure with respect to the single material, ideal gas Euler equations [122], the eigenstructure is very similar. In both cases (pressure is function of \( \rho, Y \) or pressure is a function of \( \rho, e, Y \)), the eigenvalues correspond to two non-linear waves and one contract discontinuity wave. In fact, since the material interface will travel at the contact discontinuity, allows to split the original multi-material Riemann problem, to two coupled single-material Riemann problems, as shown in Fig. A.15 and A.16.

Consequently, to solve the multi-material Riemann problem exactly, one has to do the following procedure:
- Assume an initial star region velocity, \( u^\star \).
- Based on this assumed \( u^\star \), solve each material separately, with a single material Riemann solver, assuming that the contact discontinuity is a moving wall at velocity \( u_{wall} = u^\star \). General Riemann solvers for arbitrary equations of state in the form of \( p = p(\rho) \) or \( p = p(\rho, e) \) may be found in [96].

The solution of each single-material problem is done assuming wall boundary conditions, i.e. \( p_R = p_L, \rho_R = \rho_L \), but \( u_R = -u_L + 2u_{wall} \). For example, in Fig. [A.16], when solving for material-1, the right state conditions are

\[
\mathbf{U} = \begin{bmatrix} \rho_L & \rho_L(2u_{wall} - u_L) & e_L \end{bmatrix}^T.
\]

Similarly for material-2, the left state conditions are

\[
\mathbf{U} = \begin{bmatrix} \rho_R & \rho_R(2u_{wall} - u_R) & e_R \end{bmatrix}^T.
\]

- After solving the two individual Riemann problems for material-1 and material-2, the calculated star region pressure for the two materials \( p_1^\star \) and \( p_2^\star \) is not necessarily the same. Thus, the \( u^\star \) velocity must be corrected iteratively, until \( p_1^\star = p_2^\star \).
- Once \( p_1^\star = p_2^\star \) up to a prescribed tolerance, the exact solution of the Riemann problem is the superposition of the two individual problems, i.e. the \( L \) and \( L^\star \) states from material-1 and \( R \) and \( R^\star \) states from material-2. Note that in cases of large disparities in the acoustic impedances of the materials (e.g. liquid/gas interfaces), \( p^\star \) will be very sensitive to small variations of \( u^\star \) for the stiff phase, thus under-relaxation of the corrected \( u^\star \) is advised.

As a demonstration of the aforementioned solver, the following cases will be examined and compared with PVRS solvers in literature [122]. The material properties are as follows:

*material-1*: Liquid EoS, \( p = c_L^2(\rho - \rho_{l,sat}) + p_{sat}, c_L = 1482.35 \text{ m/s, } p_{sat} = 2340 \text{ Pa, } \rho_{l,sat} = 998.16 \text{ kg/m}^3 \)

*material-2*: Gas EoS, \( p = \rho R_g T_{ref}, R_g = 287.06 \text{ J/(kgK), } T_{ref} = 293 \text{ K} \)

*Appendix A.3.1. Case A*

The initial configuration of the Riemann problem is shown in Table [A.2]. The exact solution is \( p^\star = 1430.9 \text{ Pa and } u^\star = 0.067 \text{ m/s} \). The PVRS-solver, using average states between \( L, R \) fails to properly predict the star region; in fact, it
predicts $p^* = 50666.7 \text{ Pa}$ (3440.9 \% deviation from exact) and $u^* = 0.11 \text{ m/s}$ (66.9 \% deviation from exact). On the other hand, the PVRS-solver outlined in section 3.4 predicts $p^* = 1430.9 \text{ Pa}$ (practically identical to exact solution) and $u^* = 0.066 \text{ m/s}$ (0.2 \% deviation from exact). Note that this is the same case used for validation in section 4.1.

Table A.2: Initial configuration for the Riemann problem of Appendix A.3.1.

<td>$u_R = 0 \text{ m/s}$</td>
</tr>
<tr>
<td>$p_L = 99902.8 \text{ Pa}$</td>
<td>$p_R = 1400 \text{ Pa}$</td>
</tr>
</tbody>
</table>

Appendix A.3.2. Case B

The second Riemann problem is a much more demanding case, since there is a huge pressure and density variation between the $L$, $R$ states. The initial configuration of this Riemann problem is shown in Table A.3. The exact solution is $p^* = 144.4 \text{ Pa}$ and $u^* = 2.73 \text{ m/s}$. The PVRS-solver, using average states between $L$, $R$ again fails to properly predict the star region, due to the averaging; in fact, it predicts $p^* = 20.2 \cdot 10^5 \text{ Pa}$ (1400000 \% deviation from exact) and $u^* = 4.56 \text{ m/s}$ (66.7 \% deviation from exact). On the other hand, the PVRS-solver outlined in section 3.4 predicts $p^* = 144.4 \text{ Pa}$ (practically identical to exact solution) and $u^* = 2.72 \text{ m/s}$ (0.32 \% deviation from exact).

Table A.3: Initial configuration for the Riemann problem of Appendix A.3.2.

<td>$p_R = 143 \text{ Pa}$</td>
</tr>
</tbody>
</table>
Appendix A.3.3. Case C

In this case, although the pressure and density ratios are much lower than the case in section Appendix A.3.2, the challenge is to predict the induced depressurization due to the high gas velocity. The initial configuration of this Riemann problem is shown in Table A.4. The exact solution is \( p^* = 81548 \, \text{Pa} \) and \( u^* = 2.68 \, \text{m/s} \). The PVRS-solver, using average states between \( L \), \( R \) again fails catastrophically, predicting a negative \( p^* \); it predicts \( p^* = -154923 \, \text{Pa} \) (290 \% deviation from exact) and \( u^* = 9.46 \, \text{m/s} \) (250 \% deviation from exact). On the other hand, the PVRS-solver outlined in section 3.4 predicts \( p^* = 82025 \, \text{Pa} \) (0.59 \% deviation from exact solution) and \( u^* = 2.67 \, \text{m/s} \) (0.33 \% deviation from exact).

</tbody>
</table>

Appendix A.3.4. Case D

Also, in order to demonstrate the capability in predicting temperature effects and taking into account energy equation, a case examined by Saurel et al. [126] will be discussed. This case involves interaction of vapour and liquid dodecane, modelled as ideal gas and stiffened gas respectively. The properties of the materials are:

material-1: Liquid, stiffened gas EoS, \( p = e(\gamma_L - 1)p - \gamma_L p_\infty \), \( e = c_{v,L} T + p_\infty \), \( c_{v,L} = 1077 \, \text{J/(kgK)} \), \( p_\infty = 4 \cdot 10^8 \, \text{Pa} \), \( \gamma_L = 2.35 \)

material-2: Ideal gas EoS, \( p = \rho R_g T_{ref} \), \( e = c_{v,G} T \), \( R_g = 48.9 \, \text{J/(kgK)} \), \( c_{v,G} = 1956 \, \text{J/(kgK)} \)

The initial discontinuity in this case is described in Table A.5. The exact solution with the described solver is \( p^* = 186835.8 \, \text{kg/m}^3 \), \( u^* = 140.7 \, \text{m/s} \), \( \rho_{*,L} = \)
454.9 kg/m³, $\rho_{\text{*, R}} = 3.68$ kg/m³ which is identical with the published solution.

Table A.5: Initial configuration for the Riemann problem of Appendix A.3.3.

Appendix B. Isentropic Compression

In Table B.6, isentropic compression of liquid water starting from saturation conditions ($T = 293$ K, $p = 2317$ Pa) is calculated based on the properties of [128, 129]. The temperature increase is negligible for pressure 2500 bar ($\sim 6$ K) and even for higher pressures, temperature increase is not significant in comparison to the other phenomena which take place. For example, in the previous drop simulations for impact velocity 110 m/s, the maximum pressure is 1460 bar resulting in temperature increase less than 3.5 K. The above justify the barotropic EoS which was selected and the omission of thermal effects.

Table B.6: Temperature difference for isentropic compression of liquid water. Properties are derived from [128].

Figure 6: Drop impact at velocity 110 m/s. Left figure: Iso-surface of liquid mass fraction for $Y_g = 0.5$ combined with pressure (left half) and velocity magnitude (right half). Right figure: Density gradient magnitude, different scale for the interior and the exterior of the drop. Pressure and velocity are divided by $p_{wh}$ and $u_{imp}$ respectively, whereas time is measured from the moment of the impact and it has been non-dimensionalized with $D/c_l$. 
Figure 7: Drop impact at velocity 110 m/s. Iso-surface of liquid mass fraction for $Y_g = 0.5$ combined with wall pressure (lower part) and vapour volume fraction (upper part). Pressure is divided by $p_{w,h}$ and time is measured from the moment of the impact and it has been non-dimensionalized with $D/c_l$. 
Figure 8: Comparison of the maximum wall pressure between a planar 2-D and a 2-D axisymmetric simulation at impact velocity $110 \text{ m/s}$. Wall pressure is non-dimensionalized with $p_{wh}$ and time is measured from the moment of the impact and it has been non-dimensionalized with $\tau = D/c_l$.

Figure 9: Comparison of the pressure (left slice) and the velocity magnitude (right slice) for $u_{imp} = 22.5 \text{ m/s}$ (left), $u_{imp} = 55 \text{ m/s}$ (middle) and $u_{imp} = 110 \text{ m/s}$ (right) at non-dimensional time $t = 1.48$. The iso-surface of liquid mass fraction for $Y_g = 0.5$ is also shown. Pressure and velocity are divided by $p_{wh}$ and $u_{imp}$ respectively, whereas time is measured from the moment of the impact and it has been non-dimensionalized with $D/c_l$. 

63
Figure 10: Comparison of the vapour volume fraction (upper) and wall pressure (bottom) for $u_{imp} = 22.5\, m/s$ (left), $u_{imp} = 55\, m/s$ (middle) and $u_{imp} = 110\, m/s$ (right) at non dimensional time $t = 1.48$. The iso-surface of liquid mass fraction for $Y_g = 0.5$ is also shown. Pressure is divided by $p_{wh}$ and time is measured from the moment of the impact and it has been non-dimensionalized with $D/c_l$. 
Figure 11: Later stage of drop impact at velocity 110 m/s. Left figure: Iso-surface of liquid mass fraction for $Y_g = 0.5$ combined with pressure (left slice) and velocity magnitude (right slice). Right figure: Iso-surface of liquid mass fraction for $Y_g = 0.5$ combined with wall pressure (bottom slice) and vapour volume fraction (upper slice). Pressure and velocity are divided by $p_{wh}$ and $u_{imp}$ respectively, whereas time is measured from the moment of the impact and it has been non-dimensionalized with $D/c_l$. 
Figure 12: Maximum wall pressure (left) and generated vapour volume (right) with respect to time for different impact velocities. Wall pressure is divided by $p_{wh}$, time is measured from the moment of the impact and it has been non-dimensionalized with $\tau = D/c_1$, whereas vapour volume is divided by the initial drop volume.

Figure 13: Close-up view of case 8 at non-dimensional times $t = 0.15$ (left), $t = 0.18$ (medium) and $t = 0.25$ (right). Slices of vapour volume fraction combined with iso-line of liquid mass fraction for $Y_g = 0.5$ are shown. Time has been non-dimensionalized with $D/c_1$. 

Figure 14: Close-up view of case 8 at non-dimensional times $t = 0.15$ (left), $t = 0.18$ (medium) and $t = 0.25$ (right). Slices of pressure combined with iso-line of liquid mass fraction for $Y_g = 0.5$ are shown. Time has been non-dimensionalized with $D/c_l$ and pressure with $p_{wh}$.

Figure A.15: Wave structure of the Riemann problem for the multi-material Euler equations for a general equation of state $p = f(\rho, e, Y)$.

Figure A.16: Equivalent splitting of the multi-material Riemann problem to two coupled single-material Riemann problems.
