We show that the chiral modes in circular graphene pn junctions provide an advantage for spin manipulation via spin-orbit coupling compared to semiconductor platforms. We derive the effective Hamiltonian for the spin dynamics of the junction's zero modes and calculate their quantum phases. We find a sweet spot in parameter space where the spin is fully in-plane and radially polarized for a given junction polarity. This represents a shortcut to singular spin configurations that would otherwise require spin-orbit coupling strengths beyond experimental reach.

I. INTRODUCTION

Graphene has attracted exceptional interest as a quantum material with Dirac cones at the Fermi energy and other unique electronic properties [1–3]. One appealing feature is the possibility of tuning electrostatically the charge carriers' polarity in pn junctions of linear [4–9] and circular shape [10–18]. The latter have been created by different means, such as the tip potential of a scanning tunneling microscope [10, 14, 16, 18] or by placing impurities in the substrate [11, 13]. In both approaches, experiments have shown that it is possible to single out and steer individual electronic eigenstates. Importantly, pn junctions are essential building blocks for graphene-based electron-optical elements and edge-state interferometers [14, 19–21] also exploiting the so-called snake states [9, 22, 23].

The electronic spin degree of freedom is usually neglected in the study of graphene pn junctions because of the weak atomic spin-orbit coupling (SOC) of carbon [24–27]. However, theoretical predictions followed by experimental realizations proved that strong SOC's can be induced, e.g., by proximity with transition metal dichalcogenide (TMD) substrates [28–37]. These advances open the exciting possibility of including the spin functionality in graphene-based electron optics, with the further benefit that the versatility of pn junctions allows for the design of curved waveguides for spin and charge carriers. This is particularly interesting in view of the intense current theoretical and experimental research activity on the spin dynamics triggered by SOC in curved geometries [38–41]. The effects of SOC in graphene have been also investigated in other geometries [42–45].

In this article, we investigate circular pn junctions in the presence of (i) a perpendicular magnetic field, coupled to the electronic charge (developing Landau levels

in the quantum Hall regime) and spin (through Zeeman coupling), and (ii) proximity-induced SOC's of different types. We provide the exact solution of graphene's Dirac equation for this system and formulate an effective one-dimensional (1D) model for the spin and angular dynamics of the states localized at the pn interface. This resembles the model for semiconductor rings subject to Rashba SOC (RSOC) [46], with a meaningful difference: the chiral nature of the propagating modes. We identify a remarkable sweet spot in the parameter space, where the spin eigenstates align locally with the effective magnetic field produced by the SOC. This point coincides with the Rabi condition for electronic spin resonance in a magnetic field and represents a shortcut to adiabatic spin dynamics unavailable in its semiconductor equivalent. We confirm this result within the original full model and propose a set-up to identify this sweet spot via spin interferometry, opening a promising route to spin state manipulation in graphene.

The article is organized in the following way: In Sec. II, we introduce the model system. In Sec. III, we present a low-energy model for the system under investigation, where we show the presence of the sweet spot in the parameter space. In Sec. IV, we provide a proposal for an interferometric experiment to detect the presence of this sweet spot. We discuss in Sec. V the interpretation of the experimental proposal and its range of validity. Finally, in Sec. VI, we provide our conclusions. All the technical details are presented in the Supplemental Material (SM) [47].

II. MODEL

The low-energy model for graphene with proximity-induced SOC's reads

$$\mathcal{H} = \mathcal{H}_0 + \mathcal{H}_{\text{spin}}, \quad (1)$$

where \mathcal{H}_0 is the Dirac Hamiltonian in a perpendicular magnetic field

$$\mathcal{H}_0 = v_F (\tau \sigma_x \Pi_x + \sigma_y \Pi_y) + V, \quad (2)$$

* dario.bercioux@dipc.org

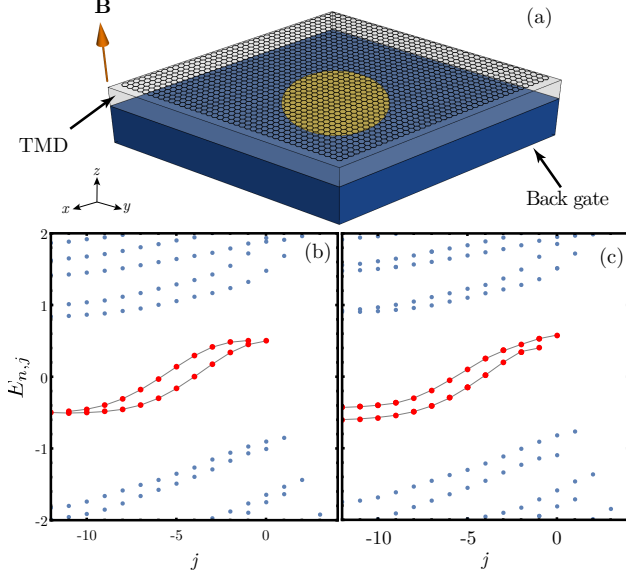

Figure 1. (a) Sketch of the system, with p and n regions drawn in yellow and blue. (b) Energy spectrum versus angular momentum j for $V_0 = 0.51$, $\xi_0 = 5.1$, $\lambda_R = 0.5$ and $\lambda_Z = \lambda_{KM} = 0$. (c) Same as in (b) but for $\lambda_Z = 0.1$. In (b) and (c), the red dots highlight the zeroth Landau levels.

with Fermi velocity v_F and kinetic momentum $\mathbf{\Pi} = -i\hbar\nabla + \frac{e}{c}\mathbf{A}$, with $\mathbf{A} = \frac{B}{2}(-y, x)$ in the symmetric gauge. Here, $\tau = \pm 1$ denotes the valley index and $\boldsymbol{\sigma} = (\sigma_x, \sigma_y)$ are Pauli matrices in sublattice space [3]. The potential

$$V(r) = V_0 \text{sign}(R - r), \quad (3)$$

defines a circular pn junction of radius R , with a p -doped region for $r < R$ (the “dot”), and a n -doped region for $r > R$. The system is sketched in Fig. 1(a). The spin-dependent part $\mathcal{H}_{\text{spin}} = \mathcal{H}_Z + \mathcal{H}_R + \mathcal{H}_{KM} + \mathcal{H}_{VZ}$ includes both Zeeman and SOC terms [28, 29, 48]:

$$\mathcal{H}_Z = \lambda_Z s_z, \quad (4a)$$

$$\mathcal{H}_R = \frac{\lambda_R}{2} (\tau \sigma_x s_y - \sigma_y s_x), \quad (4b)$$

$$\mathcal{H}_{KM} = \lambda_{KM} \tau \sigma_z s_z, \quad (4c)$$

$$\mathcal{H}_{VZ} = \lambda_{VZ} \tau s_z. \quad (4d)$$

Here $\lambda_Z = \frac{q\mu_B}{2}B$, and $\mathbf{s} = (s_x, s_y)$ denotes the Pauli matrices in spin space. The terms \mathcal{H}_R , \mathcal{H}_{KM} , and \mathcal{H}_{VZ} are the Rashba, Kane-Mele, and valley-Zeeman SOC, respectively [24, 26, 49]. Precise estimates for the SOC terms depend on the specific heterostructure, e.g., the relative orientation between graphene and substrate [35, 36]. The RSOC and the VZSOC range from few hundredths of meV up to few meV, while the KMSOC is typically much smaller [35, 37]. We are mainly concerned with the effects of the Zeeman and RSOC terms. The valley-Zeeman term can be included by means of a valley-dependent shift of the Zeeman coupling and will be considered separately in the discussion section below. For $\lambda_{VZ} = 0$,

the valley degree of freedom just leads to a degeneracy factor, so we can focus on a single valley and set $\tau = +1$. Throughout this paper, we measure lengths in units of magnetic length $\ell_B = \sqrt{\hbar c/eB} = 25.65 \text{ nm}/\sqrt{B[\text{T}]}$ and energies in units of cyclotron energy $\hbar\omega_c = \hbar v_F/\ell_B \approx 26 \text{ meV}\sqrt{B[\text{T}]}$, and assume a typical field $B \sim 1 \text{ T}$ [37].

In this model, the wave function is a four-component spinor $\Psi^T = (\Psi_{A\uparrow}, \Psi_{B\uparrow}, \Psi_{A\downarrow}, \Psi_{B\downarrow})$. The Hamiltonian \mathcal{H} commutes with the total angular momentum $J = L_z + \frac{1}{2}(\sigma_z + s_z)$, with $L_z = -i\partial_\theta$ the orbital angular momentum, hence its eigenstates $\Psi_j(\mathbf{r})$, expressed in terms of confluent hypergeometric functions [47, 50–52], can be labelled by an integer $j \in \mathbb{Z}$. The spectrum is illustrated in Figs. 1(b) and 1(c). In particular, we find two “zero-energy” Landau levels (LLs), the “top” (T) and “bottom” (B) zero modes, highlighted in red in the figures. In the absence of SOC, they have zero energy for $V_0 = 0$, but develop a dispersion in j for finite V_0 [22, 47]. Their energy at $j = 0$ and at $j \ll -1$ approaches the value of the potential $V(r)$ inside and outside the dot, respectively, see Fig. 1(b). In the presence of RSOC, the two modes acquire a spin splitting, similar to the case of a two-dimensional electron gas (2DEG) [27, 53]. A finite Zeeman coupling produces an additional vertical splitting—see Fig. 1(c). We present in the SM [47] the exact solution of the model (1), including a detailed analysis of the spin splitting as a function of λ_R .

III. EFFECTIVE 1D MODEL

In order to describe the low-energy physics around the Fermi energy (set at the charge neutrality point, $E_F = 0$), we introduce an effective 1D Hamiltonian for the zero modes localized at the pn interface. We follow an analogous derivation for a semiconductor ring with RSOC [54], see the SM [47] for details. We first perform a unitary transformation, $\mathcal{H} \rightarrow \tilde{\mathcal{H}} = U\mathcal{H}U^{-1}$, with $U = e^{i\frac{\sigma_x}{2}(\theta + \frac{\pi}{2})}e^{i\frac{s_z}{2}\theta}$. In this rotating frame, we factorize the wave function as $\tilde{\Psi} = \tilde{\psi}_0(r)\tilde{\chi}(\theta)$, where $\tilde{\psi}_0(r)$ is the sublattice spinor for the (spin degenerate) zero mode of the radial part of $\tilde{\mathcal{H}}_0$, and $\tilde{\chi}(\theta)$ is a spinor in spin space, containing the angular dependence. The projection of $\tilde{\mathcal{H}}$ onto the zero mode $\tilde{\psi}_0(r)$ leads to the effective 1D Hamiltonian controlling the dynamics of $\tilde{\chi}(\theta)$:

$$\tilde{\mathcal{H}}_{\text{eff}} = \omega_0(L_z + \Phi) + (\omega_Z - \frac{\omega_0}{2})s_z - \omega_R s_x. \quad (5)$$

The frequencies in Eq. (5) are defined by

$$\omega_0 = \left\langle \frac{\sigma_x}{r} \right\rangle_0, \quad (6a)$$

$$\omega_Z = \lambda_Z + \lambda_{KM} \langle \sigma_z \rangle_0, \quad (6b)$$

$$\omega_R = \frac{\lambda_R}{2} \langle \sigma_x \rangle_0, \quad (6c)$$

where $\langle \dots \rangle_0$ denotes the (radial) expectation value in the state $\tilde{\psi}_0(r)$. (We note that σ_x is the azimuthal component of the velocity operator in the rotating frame.) The

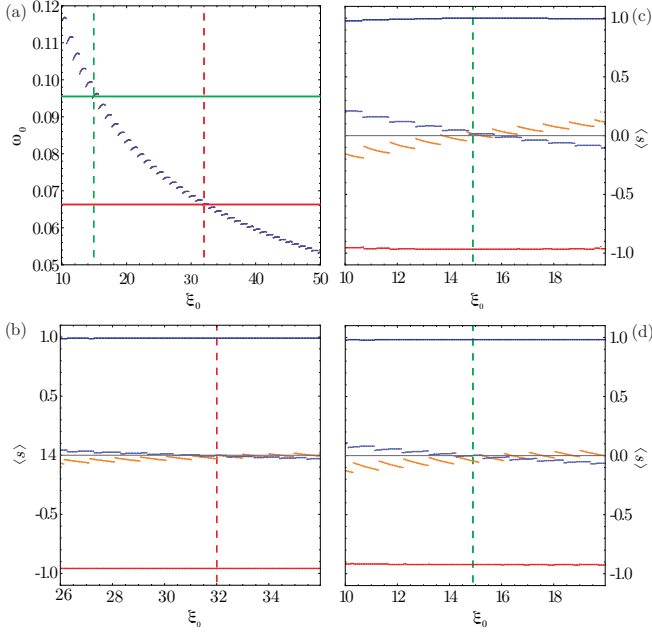

Figure 2. Sweet spot identification in the full model. (a) The angular frequency ω_0 as a function of $\xi_0 = R^2/2\ell_B^2$, at a fixed magnetic field. The green and red horizontal lines describe two representative values of $2\omega_Z$, and the vertical dashed lines the corresponding values of ξ_0 at which the resonance condition $2\omega_Z = \omega_0$ is realized. (b)-(d) The exact expectation values of the radial and perpendicular spin components in the top and bottom modes as a function of ξ_0 , for $\lambda_Z = 0.047$ and $\lambda_R = 0.2$ in (b) and for $\lambda_Z = 0.033$ and $\lambda_R = 0.2, 0.3$ in (c) and (d) respectively. In (b)-(d), the top curve shows $\langle s_r \rangle_B$, the bottom one $\langle s_r \rangle_T$, and the two central ones $\langle s_z \rangle_T$ and $\langle s_z \rangle_B$. In all the panels, $V_0 = 0.51$.

parameter $\Phi \approx \xi_0 = B\pi R^2/\Phi_0$ denotes approximately the magnetic flux through the dot in units of the flux quantum Φ_0 . Since $\tilde{\mathcal{H}}_{\text{spin}}$ is treated perturbatively, this projection is justified as long as $\hbar\omega_c$ is much larger than the Zeeman and SOC. The Hamiltonian (5) describes a 1D spinful chiral mode propagating along the curved pn interface, with angular velocity controlled by the gate voltage difference across the junction. Importantly, the polarity of the junction determines the signs of ω_0 and ω_R [55]. For $V_0 > 0$ both are positive. Inverting the polarity, $V_0 \rightarrow -V_0$, reverses the propagation direction, changing both signs. This feature has crucial implications for the experimental setup discussed below.

Diagonalizing $\tilde{\mathcal{H}}_{\text{eff}}$, we obtain the eigenvalues

$$E_{m,\pm} = \omega_0(m + \Phi) \pm \sqrt{(\omega_Z - \frac{\omega_0}{2})^2 + \omega_R^2}, \quad (7)$$

where $m \in \mathbb{Z}$ under periodic boundary conditions. This formula predicts a linear dependence of the energy on m , which we observe in the exact solution close to zero energy, and provides an approximate analytical expression for the slope of the dispersion. The corresponding

eigenstates are

$$\tilde{\chi}_{m,+} = \frac{e^{im\theta}}{\sqrt{2\pi}} \begin{pmatrix} \cos \frac{\gamma}{2} \\ -\sin \frac{\gamma}{2} \end{pmatrix}, \quad (8a)$$

$$\chi_{m,-} = \frac{e^{im\theta}}{\sqrt{2\pi}} \begin{pmatrix} \sin \frac{\gamma}{2} \\ \cos \frac{\gamma}{2} \end{pmatrix}, \quad (8b)$$

where

$$e^{i\gamma} = \frac{\omega_Z - \frac{\omega_0}{2} + i\omega_R}{\sqrt{(\omega_Z - \frac{\omega_0}{2})^2 + \omega_R^2}}. \quad (9)$$

We find a sweet spot for $\omega_Z = \frac{\omega_0}{2}$ ($\gamma = \frac{\pi}{2}$), where the spin eigenstates (8) point along the radial direction in the xy plane for any value of ω_R . This situation is remarkable. It recalls the Rabi condition for spin resonance in the rotating wave approximation (RWA), with the difference that there is no Bloch-Siegert shift [56] as a function of the driving amplitude (represented by ω_R): here, the RWA is exact. Notice that an inversion of the junction polarity, changing the chirality of the propagating spin channels ($\omega_0 \rightarrow -\omega_0$), would take the system off-resonance. This is in sharp contrast to the case of semiconductor-based Rashba rings [46, 57], where counter-propagating channels coexist, and a full in-plane alignment of the spinors is only achieved in the adiabatic limit of very large RSOC ($\omega_R \gg \omega_0$) [46].

The resonance condition, exact in the projected model (5), holds with excellent accuracy also in the full model (1). This is shown in Fig. 2, where for simplicity we set $\lambda_{\text{KM}} = 0$. Here, we define the angular frequency ω_0 as the expectation value $\langle \sigma_x/r \rangle_{\lambda_R=0}$ on the j -state closest to zero energy. From Fig. 2(a), we can see that ω_0 decreases as a function of the radius R and presents a staircase behavior due to the discreteness of j . In Figs. 2(b)-(d), we show the expectation values of the perpendicular and radial components of the spin, s_z and s_r , in the top and bottom j -states closest to zero energy for different sets of parameters. We observe that at the value of ξ_0 where the resonance condition $\omega_Z = \frac{\omega_0}{2}$ is realized, $\langle s_z \rangle$ is almost zero, whereas $\langle s_r \rangle$ is close to 1. The results in Fig. 2 show an excellent agreement between the prediction of the projected model and the full solution. In particular, they confirm that the resonance condition is independent of the RSOC. The small discrepancies are due to the coupling of the zero modes to the higher LLs via the RSOC, neglected in the projected model. We present additional results, including the effect of λ_{KM} , in the SM [47].

IV. EXPERIMENTAL PROPOSAL

We propose two setups based on linear and circular pn junctions to implement interferometric circuits for spin carriers. Thanks to the chiral nature of the propagating channels, we find that, depending on the junction polarity, the interferometers respond differently to the

Zeeman coupling ω_Z (assuming $\lambda_{KM} = 0$ for simplicity), making possible a unique geometric characterization of the propagating spin states.

Figure 3 depicts the circuits' architecture built upon n [Fig. 3(a)] and p [Fig. 3(b)] dots. Contact 1 at voltage V is the carrier source, while the grounded contacts 2 and 3 act as drains. The grounded contact 4 contributes with an empty channel. Importantly, either setup can be turned into the other by simply inverting the pn polarity, relabeling the contacts, and swapping voltages, meaning that a single sample could realize both interferometer in the laboratory.

Carriers injected from contact 1 propagate along a linear pn junction. Traveling toward contact 2, they can enter the circular pn junction with probability $0 < \tau_1 < 1$, from which they can escape at the opposite end towards contact 3 with probability $0 < \tau_2 < 1$. The tunnel barriers τ_1 and τ_2 operate as beam splitters (BSs) for the chiral modes. Their spin-dependent probability amplitudes are determined by projecting the propagating spin modes on the local basis [47].

We calculate the quantum conductance G_{21} from contact 1 to contact 2 for the zero modes following the Landauer-Büttiker approach [58, 59]. (By unitarity, $G_{21} + G_{31} = 2e^2/h$, since we are considering a single valley.) Obtaining the quantum transmission requires the combination of the BS scattering matrices [59], taking into account the spin-dependent phases $m\pi$ gathered by the carriers propagating between the tunnel barriers along the circular junction [47]. These phases are obtained by setting $E_{m,s} = 0$ in Eq. (7), where m is not necessarily an integer for open pn junctions, since periodic boundary conditions do not apply in the presence of contact leads. Figures 3(c)-(e) summarize our main results. We plot the conductance G_{21} for the two opposite junction polarities, as a function of dimensionless Rashba $Q_R = \omega_R/\omega_0$ and Zeeman $Q_Z = \omega_Z/\omega_0$ coupling strengths. Without loss of generality, we set $\tau_1 = \tau_2 = 1/2$ (50% BSs) and $\Phi \in \mathbb{N}$. Other settings can modify the relative amplitudes and phases of the patterns, but their general composition remains the same. We observe that the patterns in Figs. 3(c) and 3(d) differ by a relative $\Delta Q_Z = 1$ shift along the Zeeman axis. This shift reveals significant information on the spin-state geometry of propagating channels, as explained below.

In Fig. 3(e) we plot G_{21} for $Q_Z = 0$ (solid line) and $Q_Z = 1/2$ (dashed line). For $Q_Z = 0$, the result holds for both n and p polarities. Here we find quasi-periodic oscillations as a function of Q_R , which tend to be periodic for $Q_R \gg 1$. This limit corresponds to the regime of adiabatic spin dynamics, where the local spin quantization axis is expected to point along the radial Rashba field with $\gamma \rightarrow \pi/2$ in Eq. (8). Moreover, after a round trip around the dot, the spin carriers collect a geometric phase $\varphi_g = -\Omega/2$, with $\Omega = 2\pi(1 - \cos \gamma)$ the solid angle subtended by the spin states on the Bloch sphere. In the adiabatic limit, one finds $\varphi_g \rightarrow -\pi$. Similar results have been reported for semiconductor Rashba rings [46, 57].

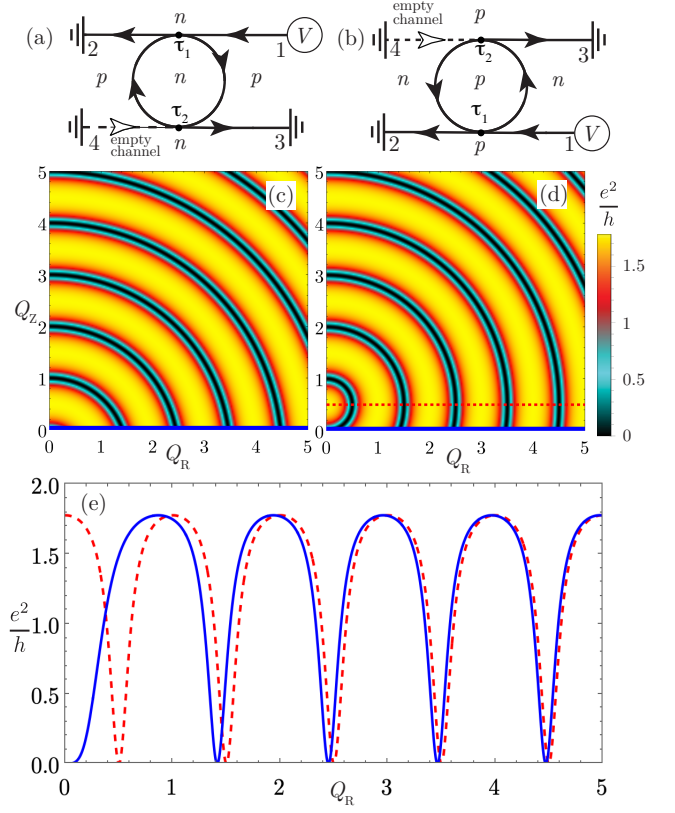

Figure 3. (a) The circuit's architecture with a n -doped dot. (b) The same as in (a), but with opposite junctions' polarity. (c)-(d) Differential conductance G_{21} for the circuits in (a) and (b), respectively, as a function of the dimensionless Rashba and Zeeman coupling strengths. (e) Cut of the differential conductance for the cases in (c) and (d) with $Q_Z = 0$ (blue line) and for the case in (d) with $Q_Z = 1/2$ (red dashed line).

The two polarities respond very differently to Q_Z . For the n dot [see Eq. (9) and Fig. 3(c)], we find that Q_Z acts to the detriment of in-plane spinor polarization, which still requires large RSOC intensities Q_R . On the contrary, for the p dot [see Eq. (9) and Figs. 3(d) and 3(e)], at the sweet spot $Q_Z = 1/2$ we find perfectly periodic oscillations corresponding to fully in-plane spin states ($\gamma = \pi/2$) regardless of the RSOC intensity, picking up a geometric phase $\varphi_g = -\pi$.

V. DISCUSSION

All relevant features of Fig. 3(d) are captured by a low-order semiclassical expansion of the conductance in terms of Feynman paths corresponding to single windings around the p dot [47]. In this approximation, we find

$$G_{21} \approx 1 + \cos \phi_{AB} \cos \phi_S, \quad (10)$$

with

$$\phi_{AB} = 2\pi\Phi, \quad (11a)$$

$$\phi_S = 2\pi\sqrt{\left(Q_Z - \frac{1}{2}\right)^2 + Q_R^2}, \quad (11b)$$

where ϕ_{AB} and ϕ_S are independent phase contributions originating in the orbital and spin degrees of freedom, respectively. Equation (10) reproduces well the pattern of Fig. 3(d) showing circular wavefronts centered at $Q_R = 0$, $Q_Z = 1/2$. For $Q_Z = 0$, we find from Eq. (10) that $\phi_S = 2\pi Q_R \sin \gamma - \pi \cos \gamma = 2\pi Q_R \sin \gamma - (\pi + \varphi_g)$. This phase reduces to $\phi_S \approx 2\pi Q_R$ in the adiabatic limit $Q_R \gg 1$, leading to periodic oscillations of G_{21} as a function of Q_R . Thus, a strong RSOC drives the spin eigenstates to be in-plane, such that $\gamma \rightarrow \pi/2$ and $\varphi_g \rightarrow -\pi$. The physical realization of this formal limit is difficult in the laboratory due to the required field intensities. Alternatively, we find here a shortcut by setting $Q_Z = 1/2$. In this sweet spot, the spin phase contribution reduces exactly to $\phi_S = 2\pi Q_R$ even for weak RSOC fields, which assures in-plane spin eigenstates that introduce a π phase-shift of purely geometric origin.

We emphasize that this precise characterization of the propagating spin channels boils down to their chiral nature, in contrast to the case of semiconductor Rashba rings, where counter-propagating modes coexist [46, 57, 60]. The chirality also protects the sweet spot from the effect of random impurities. Moreover, we expect that small deviations from a perfectly circular shape, breaking the rotational symmetry might induce small oscillations of the out-of-plane component of the spin and thus blur the sweet spot, but will not qualitatively alter the physics discussed here [61].

Finally, we briefly address the effect of the VZSOC. In the effective model (5), it leads to a valley-dependent shift $\omega_Z \rightarrow \omega_Z + \tau\lambda_{VZ}$. Hence, at $\omega_Z = \omega_0/2$, the spin states (8) will have a residual out-of-plane component, opposite at the two valleys. The valley-resolved conductances will be periodic functions of Q_R only for

$\lambda_R \gg \lambda_{VZ}$ [47], see Eqs. (10) and (11b). The selection of substrates inducing the weakest possible VZSOC [35, 36] is thus essential to observing the effects described in this work.

VI. CONCLUSIONS

We have shown that the chiral spin channels in curved graphene pn junctions with proximitized SOC's can be precisely characterized and controlled. We uncovered a sweet spot in the parameter space enabling an efficient manipulation of spin-state configurations without requiring a strong RSOC, which is difficult to achieve experimentally. This opens up new possibilities for exploring quantum-state geometry and advancing spintronics in graphene. Curved pn junctions thus offer a versatile platform for investigating spin dynamics phenomena induced by SOC's, providing an alternative to traditional semiconductor systems.

SUPPLEMENTAL MATERIAL

Chiral spin channels in curved graphene pn junctions

I. THE HAMILTONIAN

In this section, we illustrate the complete low-energy Hamiltonian for a graphene monolayer with proximitized spin-orbit couplings (SOCs). Following [29] (see also [48]), the full Hamiltonian reads:

$$\mathcal{H} = \mathcal{H}_0 + \mathcal{H}_\Delta + \mathcal{H}_Z + \mathcal{H}_R + \mathcal{H}_{\text{KM}} + \mathcal{H}_{\text{VZ}}, \quad (\text{SE1})$$

where

$$\mathcal{H}_0 = v_F (\tau_z \sigma_x \Pi_x + \sigma_y \Pi_y) + V, \quad (\text{SE2a})$$

$$\mathcal{H}_\Delta = \Delta \sigma_z, \quad (\text{SE2b})$$

$$\mathcal{H}_Z = \lambda_Z s_z, \quad (\text{SE2c})$$

$$\mathcal{H}_R = \frac{\lambda_R}{2} (\tau_z \sigma_x s_y - \sigma_y s_x), \quad (\text{SE2d})$$

$$\mathcal{H}_{\text{KM}} = \lambda_{\text{KM}} \tau_z \sigma_z s_z, \quad (\text{SE2e})$$

$$\mathcal{H}_{\text{VZ}} = \lambda_{\text{VZ}} \tau_z s_z. \quad (\text{SE2f})$$

Here, $v_F \approx 10^6$ m/s is the graphene's Fermi velocity, $\mathbf{\Pi} = -i\hbar\nabla + \frac{e}{c}\mathbf{A}$ the kinetic momentum, $\mathbf{A} = \frac{B}{2}(-y, x, 0)$ the vector potential in the symmetric gauge (we assume $B > 0$), and $V(\mathbf{r})$ the potential defining the circular pn junction. The symbols $\boldsymbol{\tau}/\boldsymbol{\sigma}/\mathbf{s}$ denote the valley/sublattice/spin Pauli matrices. The Hamiltonian (SE1) is diagonal in valley space. It includes the sublattice-symmetry breaking term \mathcal{H}_Δ , the Zeeman term \mathcal{H}_Z (with $\lambda_Z = \frac{g_s \mu_B}{2} B$), the Kane and Mele (or intrinsic) SOC \mathcal{H}_{KM} , the Rashba SOC \mathcal{H}_R , and the valley-Zeeman SOC \mathcal{H}_{VZ} . For completeness, we include the sublattice-symmetry breaking term \mathcal{H}_Δ , which we have neglected in the main text.

The wave function is an 8-component spinor

$$(\Psi_{A\uparrow}, \Psi_{B\uparrow}, \Psi_{A\downarrow}, \Psi_{B\downarrow}, \Psi'_{A\uparrow}, \Psi'_{B\uparrow}, \Psi'_{A\downarrow}, \Psi'_{B\downarrow}), \quad (\text{SE3})$$

where the unprimed and primed components are the amplitudes at the valley K ($\tau_z = +1$) and K' ($\tau_z = -1$), respectively. The Hamiltonian \mathcal{H} is invariant under the time-reversal operation $\mathcal{T} = i s_y \tau_x \mathcal{K}$ up to the inversion of the magnetic field:

$$\mathcal{T} \mathcal{H}(\mathbf{B}) \mathcal{T}^\dagger = \mathcal{H}(-\mathbf{B}), \quad (\text{SE4})$$

and commutes with the total angular momentum operator $J = L_z + \frac{1}{2}(\tau_z \sigma_z + s_z)$.

Since \mathcal{H} is diagonal in valley space, we will focus on a single valley ($\tau_z = +1$) and omit the valley index. Then, the wave function Ψ is a four-component spinor in sublattice/spin space, $\Psi^T = (\Psi_{A\uparrow}, \Psi_{B\uparrow}, \Psi_{A\downarrow}, \Psi_{B\downarrow})$. The single-valley Hamiltonians are related by the unitary transformation

$$\mathcal{H}_{\tau_z=-1}(\Delta, \lambda_{\text{VZ}}) = i\sigma_y \mathcal{H}_{\tau_z=+1}(-\Delta, -\lambda_{\text{VZ}})(-i\sigma_y). \quad (\text{SE5})$$

Using this identity, one can find the eigenstates at the valley $\tau_z = -1$ once the eigenstates at the valley $\tau_z = +1$ are determined.

Before closing this section, we notice that we express energy in units of the relativistic cyclotron energy $\hbar\omega_c$, length in units of the magnetic length ℓ_B , and wave vectors in units of ℓ_B^{-1} , with

$$\ell_B = \sqrt{\frac{\hbar c}{eB}} = \frac{26}{\sqrt{B[\text{T}]}} \text{ nm}, \quad \hbar\omega_c = \frac{\hbar v_F}{\ell_B} = 26\sqrt{B[\text{T}]} \text{ meV}, \quad \hbar\omega_Z = \frac{g_s \mu_B}{2} B = 5.8 \times 10^{-2} B[\text{T}] \text{ meV}.$$

We set $e = \hbar = v_F = 1$ unless specified otherwise.

II. EXACT MODEL SOLUTION

In this section, we provide the exact solution of the problem of graphene's Landau levels in the symmetric gauge in the presence of SOCs and a constant potential. (See [43, 53] for the solution to this problem in the Landau gauge.) Since we work in a given valley, the valley-Zeeman term can be absorbed into the Zeeman term and will be omitted below. The single-valley Hamiltonian ($\tau_z = +1$) in the symmetric gauge commutes with the total angular momentum

$$J = L_z + \frac{\sigma_z}{2} + \frac{s_z}{2}, \quad (\text{SE6})$$

with $L_z = -i\partial_\theta$, hence the eigenfunctions can be labeled by the eigenvalues of J , which span the set of integers, and take the form

$$\Psi_j(\mathbf{r}) = \frac{e^{i(j - \frac{\sigma_z}{2} - \frac{s_z}{2})\theta}}{\sqrt{2\pi}} \psi_j(r), \quad (\text{SE7})$$

where (r, θ) are polar coordinates and $j \in \mathbb{Z}$. The radial spinor $\psi_j(r)$ is a solution of the equation

$$(\mathcal{H}_j - E) \psi_j = 0, \quad (\text{SE8})$$

where

$$\mathcal{H}_j = e^{-i(j - \frac{\sigma_z}{2} - \frac{s_z}{2})\theta} \mathcal{H} e^{i(j - \frac{\sigma_z}{2} - \frac{s_z}{2})\theta} \quad (\text{SE9})$$

is the radial Hamiltonian in a fixed j sector:

$$\mathcal{H}_j - E = \begin{pmatrix} -\mu_+ & -i(\frac{d}{dr} + \frac{j}{r} + \frac{r}{2}) & 0 & 0 \\ i(-\frac{d}{dr} + \frac{j-1}{r} + \frac{r}{2}) & -\mu_- & -i\lambda_R & 0 \\ 0 & i\lambda_R & -\nu_- & -i(\frac{d}{dr} + \frac{j+1}{r} + \frac{r}{2}) \\ 0 & 0 & i(-\frac{d}{dr} + \frac{j}{r} + \frac{r}{2}) & -\nu_+ \end{pmatrix}. \quad (\text{SE10})$$

Here, we have introduced the auxiliary symbols

$$\mu_{\pm} = E - V - (\lambda_Z \pm \lambda_{\text{KM}} \pm \Delta), \quad (\text{SE11a})$$

$$\nu_{\pm} = E - V - (-\lambda_Z \pm \lambda_{\text{KM}} \mp \Delta), \quad (\text{SE11b})$$

and we will use the notation

$$\mu = \mu_+ \mu_- = (E - V - \lambda_Z)^2 - (\lambda_{\text{KM}} + \Delta)^2, \quad (\text{SE12})$$

$$\nu = \nu_+ \nu_- = (E - V + \lambda_Z)^2 - (\lambda_{\text{KM}} - \Delta)^2. \quad (\text{SE13})$$

In terms of the variable $\xi = r^2/2$, we find

$$\mathcal{H}_j - E = \begin{pmatrix} -\mu_+ & -i\sqrt{2\xi} \left(\frac{d}{d\xi} + \frac{1}{2} + \frac{j}{2\xi} \right) & 0 & 0 \\ i\sqrt{2\xi} \left(-\frac{d}{d\xi} + \frac{1}{2} + \frac{j-1}{2\xi} \right) & -\mu_- & -i\lambda_R & 0 \\ 0 & i\lambda_R & -\nu_- & -i\sqrt{2\xi} \left(\frac{d}{d\xi} + \frac{1}{2} + \frac{j+1}{2\xi} \right) \\ 0 & 0 & i\sqrt{2\xi} \left(-\frac{d}{d\xi} + \frac{1}{2} + \frac{j}{2\xi} \right) & -\nu_+ \end{pmatrix}. \quad (\text{SE14})$$

The general solution of Eq. (SE8) can be expressed in terms of confluent hypergeometric functions [50]. In the following, we will present the solutions separately for $j \geq 0$ and $j < 0$.

A. Case $j \geq 0$

First, we assume $j > 0$. The solutions of graphene's Landau levels problem without SOCs (see, e.g., [22, 51, 52]) and with SOCs in the Landau gauge [43, 53] suggest the following ansatz:

$$\psi_j(\xi) = e^{-\xi/2} \xi^{j/2} \begin{pmatrix} d_1 \xi^{-1/2} M(a, j, \xi) \\ id_2 M(a, j+1, \xi) \\ d_3 M(a, j+1, \xi) \\ id_4 \xi^{1/2} M(a, j+2, \xi) \end{pmatrix}, \quad (\text{SE15})$$

where d_i are constant coefficients (for simplicity, we omit the index j on the coefficients), and $M(a, b, \xi)$ denotes the confluent hypergeometric function of the first kind [50], regular at the origin. The parameter a will be determined below. By using recurrence relations between confluent hypergeometric functions, Eq. (SE14) is converted into a linear system for the coefficients d_i :

$$\begin{pmatrix} -\mu_+ & \sqrt{2}j & 0 & 0 \\ \sqrt{2}\left(1 - \frac{a}{j}\right) & -\mu_- & -\lambda_R & 0 \\ 0 & -\lambda_R & -\nu_- & \sqrt{2}(j+1) \\ 0 & 0 & \sqrt{2}\left(1 - \frac{a}{j+1}\right) & -\nu_+ \end{pmatrix} \begin{pmatrix} d_1 \\ d_2 \\ d_3 \\ d_4 \end{pmatrix} = 0. \quad (\text{SE16})$$

The existence of a non-trivial solution requires the vanishing of the determinant of the coefficient matrix:

$$[2(a-j) + \mu][2(a-j-1) + \nu] - \lambda_R^2 \mu_+ \nu_+ = 0. \quad (\text{SE17})$$

The solution of the linear system (SE16) is (up to an overall constant)

$$\begin{pmatrix} d_1 \\ d_2 \\ d_3 \\ d_4 \end{pmatrix} = \begin{pmatrix} \sqrt{2}j \\ \mu_+ \\ -\frac{2(a-j)+\mu}{\lambda_R} \\ \frac{\sqrt{2}(a-j-1)[2(a-j)+\mu]}{\lambda_R \nu_+ (j+1)} \end{pmatrix}. \quad (\text{SE18})$$

A second solution, singular at the origin, is built using the confluent hypergeometric function of the second kind $U(a, b, \xi)$ [50]:

$$\psi_j(\xi) = e^{-\xi/2} \xi^{j/2} \begin{pmatrix} d_1 \xi^{-1/2} U(a, j, \xi) \\ i d_2 U(a, j+1, \xi) \\ d_3 U(a, j+1, \xi) \\ i \xi^{1/2} d_4 U(a, j+2, \xi) \end{pmatrix}. \quad (\text{SE19})$$

The corresponding linear system for the coefficients d_i is

$$\begin{pmatrix} -\mu_+ & \sqrt{2}(j-a) & 0 & 0 \\ \sqrt{2} & -\mu_- & -\lambda_R & 0 \\ 0 & -\lambda_R & -\nu_- & \sqrt{2}(j+1-a) \\ 0 & 0 & \sqrt{2} & -\nu_+ \end{pmatrix} \begin{pmatrix} d_1 \\ d_2 \\ d_3 \\ d_4 \end{pmatrix} = 0, \quad (\text{SE20})$$

and the determinant equation is the same as in Eq. (SE17). The solution of this linear system gives

$$\begin{pmatrix} d_1 \\ d_2 \\ d_3 \\ d_4 \end{pmatrix} = \begin{pmatrix} \sqrt{2}(j-a) \\ \mu_+ \\ -\frac{2(a-j)+\mu}{\lambda_R} \\ -\frac{\sqrt{2}[2(a-j)+\mu]}{\lambda_R \nu_+} \end{pmatrix}. \quad (\text{SE21})$$

The solution for $j = 0$ can now be obtained by taking the limit $j \rightarrow 0$ in the previous formulas and using the following identities:

$$\lim_{j \rightarrow 0} j M(a, j, \xi) = a \xi M(a+1, 2, \xi), \quad (\text{SE22})$$

$$U(a, 0, \xi) = \xi U(a+1, 2, \xi). \quad (\text{SE23})$$

B. Case $j < 0$

In this case, the correct ansatz for the solution regular at the origin reads

$$\psi_j(\xi) = e^{-\xi/2} \xi^{-j/2} \begin{pmatrix} d_1 \xi^{1/2} M(a+1, -j+2, \xi) \\ i d_2 M(a, -j+1, \xi) \\ d_3 M(a, -j+1, \xi) \\ i d_4 \xi^{-1/2} M(a-1, -j, \xi) \end{pmatrix}. \quad (\text{SE24})$$

Then, the algebraic equation for the coefficients d_i is

$$\begin{pmatrix} -\mu_+ & \sqrt{2}\frac{a}{1-j} & 0 & 0 \\ \sqrt{2}(j-1) & -\mu_- & -\lambda_R & 0 \\ 0 & -\lambda_R & -\nu_- & \sqrt{2}\frac{1-a}{j} \\ 0 & 0 & \sqrt{2}j & -\nu_+ \end{pmatrix} \begin{pmatrix} d_1 \\ d_2 \\ d_3 \\ d_4 \end{pmatrix} = 0. \quad (\text{SE25})$$

The condition of vanishing determinant reads

$$(2a + \mu)(2a - 2 + \nu) - \lambda_R^2 \mu_+ \nu_+ = 0, \quad (\text{SE26})$$

and the solution of the linear system (up to an overall constant) is

$$\begin{pmatrix} d_1 \\ d_2 \\ d_3 \\ d_4 \end{pmatrix} = \begin{pmatrix} \frac{\sqrt{2}\lambda_R \nu_+ a}{1-j} \\ \lambda_R \mu_+ \nu_+ \\ -\nu_+(2a + \mu) \\ -\sqrt{2}j(2a + \mu) \end{pmatrix}. \quad (\text{SE27})$$

The second solution, singular at the origin, is given by

$$\psi_j(\xi) = e^{-\xi/2} \xi^{-j/2} \begin{pmatrix} d_1 \xi^{1/2} U(a+1, -j+2, \xi) \\ i d_2 U(a, -j+1, \xi) \\ d_3 U(a, -j+1, \xi) \\ i d_4 \xi^{-1/2} U(a-1, -j, \xi) \end{pmatrix}. \quad (\text{SE28})$$

The associated linear system is

$$\begin{pmatrix} -\mu_+ & -\sqrt{2}a & 0 & 0 \\ \sqrt{2} & -\mu_- & -\lambda_R & 0 \\ 0 & -\lambda_R & -\nu_- & \sqrt{2}(1-a) \\ 0 & 0 & \sqrt{2} & -\nu_+ \end{pmatrix} \begin{pmatrix} d_1 \\ d_2 \\ d_3 \\ d_4 \end{pmatrix} = 0, \quad (\text{SE29})$$

with the same determinant equation as in Eq. (SE26), and the solution given by

$$\begin{pmatrix} d_1 \\ d_2 \\ d_3 \\ d_4 \end{pmatrix} = \begin{pmatrix} -\sqrt{2}\lambda_R \nu_+ a \\ \lambda_R \mu_+ \nu_+ \\ -\nu_+(2a + \mu) \\ -\sqrt{2}(2a + \mu) \end{pmatrix}. \quad (\text{SE30})$$

We note in passing that, by taking the limit $j \rightarrow 0$ in the formulas above, we recover the solution for $j = 0$ given in Sec. II A.

C. General solution

The two determinant equations (SE17) and (SE26) can be merged into a single equation:

$$[2(a - j\Theta(j)) + \mu][2(a - j\Theta(j) - 1) + \nu] - \lambda_R^2 \mu_+ \nu_+ = 0, \quad (\text{SE31})$$

where $\Theta(x)$ is the Heaviside function. (We adopt the convention $\Theta(0) = 1$.) This condition admits the solutions $a = a_{\pm}$ given by

$$a_{\pm} = j\Theta(j) - \frac{1}{4} \left[\mu + \nu - 2 \pm \sqrt{(\mu - \nu + 2)^2 + 4\lambda_R^2 \mu_+ \nu_+} \right]. \quad (\text{SE32})$$

We denote by $\psi_j^<(\xi)$ the wave functions regular at the origin, Eqs. (SE15) and (SE24), and by $\psi_j^>(\xi)$ the wave functions singular at the origin, Eqs. (SE19) and (SE28). The eigenspace of energy E and total angular momentum j is then spanned by the linear combinations of the four solutions obtained by taking $\psi_j^<$ and $\psi_j^>$ with $a = a_{\pm}$ in Eq. (SE32):

$$\psi_j(\xi) = c_1 \psi_{j,a_+}^<(\xi) + c_2 \psi_{j,a_-}^<(\xi) + c_3 \psi_{j,a_+}^>(\xi) + c_4 \psi_{j,a_-}^>(\xi).$$

As we will see below, the quantized energy eigenvalues (Landau levels) are obtained by imposing appropriate conditions on this general solution. In Sec. III we consider the case of a uniform system, where the quantization condition originates simply from the requirement of normalizability. In Sec. IV we consider the case of a circular pn junction, where the quantization condition arises from the combination of the requirements of normalizability and continuity of the wave function.

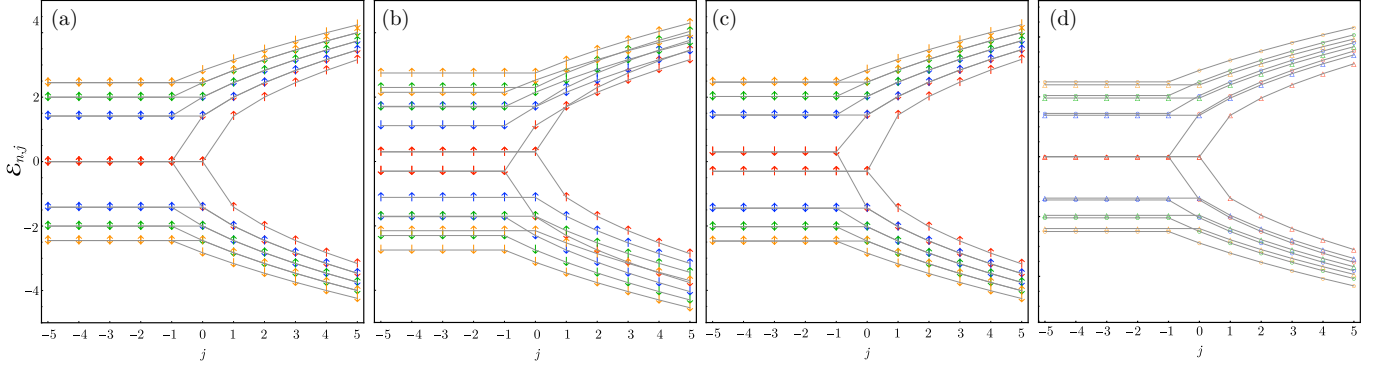

Figure SF1. Landau level spectrum in the symmetric gauge. (a) Spin degenerate case, with $\lambda_Z = \lambda_{KM} = \lambda_R = \Delta = 0$. (b) Case with only Zeeman splitting, with $\lambda_Z = 0.3$. (c) Case with only intrinsic SOC, with $\lambda_{KM} = 0.3$. (d) Case with only Rashba SOC, with $\lambda_R = 0.3$. In panels (a) to (c), the arrows are associated with the eigenvalues of s_z . In all panels, the color refers to the radial quantum number n : red to $n = 0$, blue to $n = 1$, green to $n = 2$ and orange to $n = 3$.

III. UNIFORM SYSTEM

For a uniform system ($V = 0$) we have to select the solutions regular at the origin, Eqs. (SE15) and (SE24), which involve the functions $M(a, b, \xi)$. Then normalizability requires that the first argument of M is a non-positive integer $-n$, where n is interpreted as the radial quantum number. As a result, we find two sets of Landau levels, obtained by solving the equations

$$\begin{cases} a_{\pm}(E) = -n & n = 0, 1, 2, \dots, \text{ for } j \geq 0 \\ a_{\pm}(E) - 1 = -n & n = 0, 1, 2, \dots, \text{ for } j < 0 \end{cases}, \quad (\text{SE33})$$

with a_{\pm} in Eq. (SE32). For the correct counting of the solutions, one should notice the following:

- Case $j = 0$: for $n = 0$ (i.e., $a = 0$) the solution of Eq. (SE31) with $\mu_+ = 0$ must be omitted, because all wave function components vanish, see Eq. (SE18).
- Case $j < 0$: for $n = 0$ (i.e., $a = 1$) only the solution of Eq. (SE31) with $\nu_+ = 0$ is allowed because the first three components of the wave function (which are not normalizable functions if $a = 1$) have a vanishing coefficient, see Eq. (SE27). For $n = 1$ (i.e., $a = 0$) the solution of Eq. (SE31) with $\mu_+ = 0$ must be omitted for the same reason as in the case $j = 0$ above.

The quantization equation (SE31) is quartic in the energy and can be solved explicitly. However, the general expression of the solutions is cumbersome and not particularly illuminating. Below, we briefly discuss few special cases and give the explicit formulas for the corresponding energy eigenvalues.

- If the Rashba SOC vanishes, Eq. (SE31) decouples into two separate equations, each giving a set of spin-polarized Landau levels. From $2(a - j\Theta(j)) + \mu = 0$ we find the spin-up levels

$$E_{n,j,\alpha,-} = \lambda_Z + \alpha \sqrt{2(n + j\Theta(j)) + (\lambda_{KM} + \Delta)^2}, \quad n = 0, 1, 2, \dots, \quad j = 0, \pm 1, \pm 2, \dots, \quad \alpha = \pm 1, \quad (\text{SE34})$$

where for $n = 0$ and $j \leq 0$ only the level $E_{0,j} = \lambda_Z - \lambda_{KM} - \Delta$ must be kept. From $2(a - j\Theta(j) - 1) + \nu = 0$ we find the spin-down levels

$$E_{n,j,\alpha,+} = -\lambda_Z + \alpha \sqrt{2(n + (j+1)\Theta(j)) + (\lambda_{KM} - \Delta)^2}, \quad n = 0, 1, 2, \dots, \quad j = 0, \pm 1, \pm 2, \dots, \quad \alpha = \pm 1, \quad (\text{SE35})$$

where for $n = 0$ and $j < 0$ only the level $E_{0,j} = -\lambda_Z + \lambda_{KM} - \Delta$ must be kept. For $\lambda_Z = \lambda_{KM} = \Delta = 0$, the expressions in Eqs. (SE34) and (SE35) coincide with the Landau level formula in the symmetric gauge (see, e.g., [22]) after the replacement $j = j' \pm \frac{1}{2}$ for spin up/down states, with j' half-integer.

- If we have only a finite Rashba SOC and all the other couplings are set to zero, the Landau levels obtained by solving Eq. (SE31) are given by (see also [53])

$$E_{n,j,\alpha,\beta} = \alpha \left[2[n + (j+1)\Theta(j)] - 1 + \frac{\lambda_R^2}{2} + \beta \sqrt{\left(1 - \frac{\lambda_R^2}{2}\right)^2 + 2\lambda_R^2[n + (j+1)\Theta(j)]} \right]^{\frac{1}{2}}, \quad \alpha, \beta = \pm 1. \quad (\text{SE36})$$

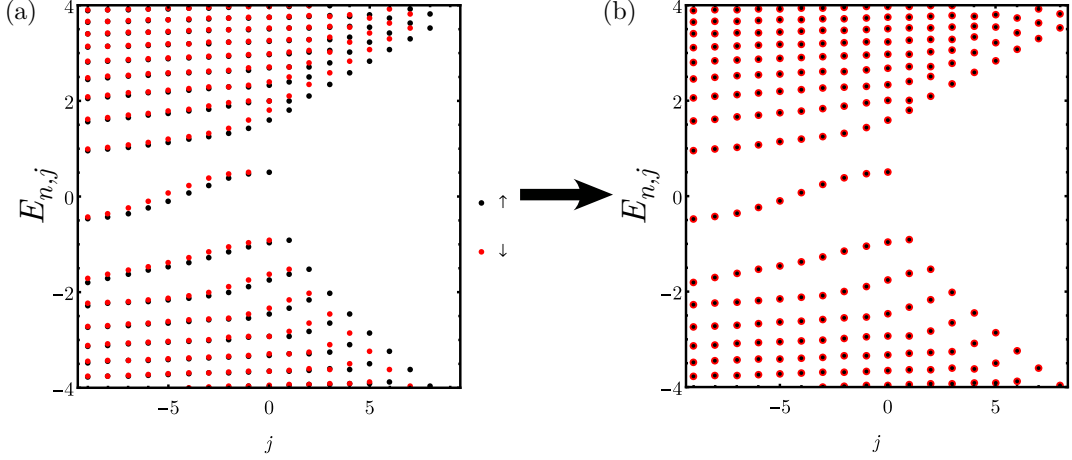

Figure SF2. (a) Spectrum of the circular pn junction with $\xi_0 = 5.1$ and $V_0 = 0.51$ as a function of j for vanishing SOCs and Zeeman coupling. (b) The same as in (a) but with the spin-down states translated by 1 along the j -axis, showing that they coincide, as expected because of spin degeneracy.

For the correct counting of the states, one should keep in mind the remarks at the beginning of this section. It is interesting to observe that at the lowest order in λ_R one finds

$$E_{n,j,\alpha,\beta} \approx \alpha \left(1 + \beta \frac{\lambda_R^2}{2} \right) \sqrt{2[n + (j+1)\Theta(j)] + \beta - 1}. \quad (\text{SE37})$$

We see that the effect of a small Rashba SOC is essentially a renormalization of the cyclotron frequency. We note in passing that the states corresponding to the two sets of levels in Eq. (SE37) are not eigenstates of s_z .

We illustrate in Fig. SF1 the exact Landau level spectrum in the symmetric gauge for four relevant cases. We observe that, in all cases, at a fixed value of the radial quantum number n , the energy is independent of the angular quantum number j for $j \leq n$ or $j \leq n - 1$. In the first three panels, we set $\lambda_R = 0$, hence the spin projection in the z direction is a good quantum number and the eigenfunctions describe spin states polarized along the z axis. In panel SF1(a) we present the spin degenerate case with $\lambda_Z = \lambda_{\text{KM}} = \lambda_R = \Delta = 0$. The spectra of spin-up and spin-down states appear to have a relative horizontal shift, because we label our states with the total angular momentum j . They coincide if we plot the spin-up spectrum versus $j' = j - \frac{1}{2}$ and the spin-down spectrum versus $j' = j + \frac{1}{2}$. This shift is the reason why the lowest-energy states with $j \geq 0$ appear singly degenerate. If only the Zeeman coupling is active, see panel SF1(b), we observe the usual energy shift, upwards for spin-up states and downwards for spin-down states. In the case that only the intrinsic SOC is active, illustrated in panel SF1(c), we see that the spin degeneracy of the zero-energy Landau level is lifted, while all other levels remain spin degenerate.

Finally, in panel SF1(d) we show the spectrum when only the Rashba SOC is active. In this case, the projection of the spin along the z axis is no longer a good quantum number, because the SOC mixes spin-up and spin-down states. As a result, the spin degeneracy of all levels is lifted, with the exception of the zero-energy level, which remains doubly degenerate at zero energy. This residual degeneracy is a result of the fact that the zero-energy states have support on a single sublattice [43, 53].

IV. LANDAU LEVELS IN A PN JUNCTION

Next, we discuss the exact solution of the Landau level problem in the case of a pn junction. We assume that the potential has the following profile:

$$V(r) = V_0 \text{sign}(R - r), \quad V_0 > 0, \quad (\text{SE38})$$

namely, $V = V_0$ within a disc of radius R and $V = -V_0$ outside the disc. We use $\xi_0 = R^2/2$ as a measure for the size of the circular junction. Using the solutions found in Sec. II, we write the radial wave function as

$$\psi(\xi) = \begin{cases} c_1 \psi_{a+,-V_0}^<(\xi) + c_2 \psi_{a-,-V_0}^<(\xi) & \xi < \xi_0 \\ c_3 \psi_{a+,V_0}^>(\xi) + c_4 \psi_{a-,V_0}^>(\xi) & \xi > \xi_0 \end{cases}. \quad (\text{SE39})$$

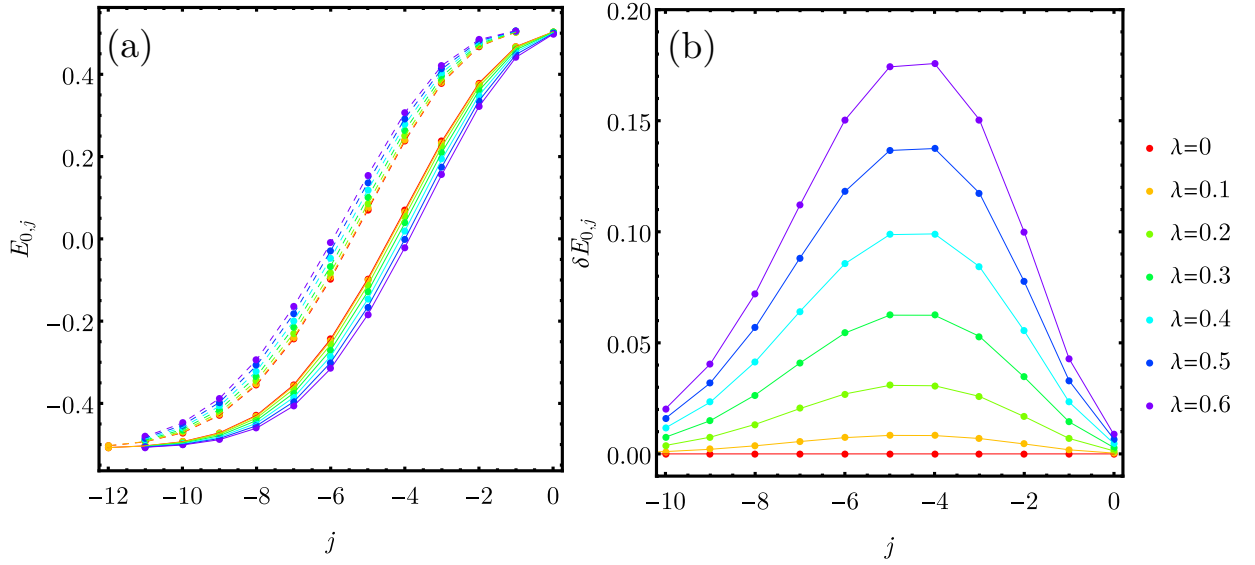

Figure SF3. (a) The energy spectrum of the zero modes as a function of the total angular momentum j for several values of the Rashba SOC. (b) The zero-mode splitting defined in Eq. (SE43) as a function of the total angular momentum j for several values of the Rashba SOC. For both panels, the values of the Rashba SOC are indicated on the side of the panel (b).

Here we omit the index j , being understood that we work at fixed angular momentum, and we append two indexes to indicate the values of the parameter a and of the potential V . The eigenenergies and the eigenstates are obtained by matching the wave functions at the boundary of the disc $\xi = \xi_0$:

$$c_1 \psi_{a+,-V_0}^<(\xi_0) + c_2 \psi_{a-,-V_0}^<(\xi_0) = c_3 \psi_{a+,V_0}^>(\xi_0) + c_4 \psi_{a-,V_0}^>(\xi_0). \quad (\text{SE40})$$

In analogy to the case of a linear junction [22, 53], we obtain a linear system for the c_i , with the matrix of coefficients given by

$$\mathbf{W} = [\psi_{a+,-V_0}^<(\xi_0) \quad \psi_{a-,-V_0}^<(\xi_0) \quad -\psi_{a+,V_0}^>(\xi_0) \quad -\psi_{a-,V_0}^>(\xi_0)]. \quad (\text{SE41})$$

The allowed energy eigenvalues are found by solving the equation

$$\det \mathbf{W} = 0. \quad (\text{SE42})$$

Once the eigenvalues are determined, the corresponding normalized eigenstates can be calculated from Eq. (SE39) using the solution of the linear system (SE40).

In Fig. SF2 we show the exact spectrum of the circular pn junction obtained from the numerical solution of Eq. (SE42) in the absence of Rashba SOC for the spin-degenerate case. The effect of the potential step is that the levels acquire a dispersion in j . As observed in the uniform case discussed in Sec. III, the spectra for spin-up and spin-down states appear horizontally shifted one with respect to the other, which results from labeling the states with the total angular momentum j . As shown in panel SF2(b), when the spin-down spectrum is shifted to the right by 1, they do overlap. This observation suggests defining the splitting of the energy levels as the difference $|E_{n,j,\alpha,+} - E_{n,j-1,\alpha,-}|$, which vanishes in the spin-degenerate case.

We now focus on the two lowest-energy levels, which we refer to as the top and bottom modes and denote as $E_{0,j}^T$ and $E_{0,j}^B$ with corresponding radial wave functions $\psi_j^T(\xi)$ and $\psi_j^B(\xi)$. In Fig. SF3(a) we show their dispersion as a function of the total angular momentum j for different values of the Rashba SOC. We see that the j -dependence around zero energy is linear with good approximation. In Fig. SF3(b) we show the energy splitting of the zero modes, defined as

$$\delta E_{0,j} = |E_{0,j}^T - E_{0,j-1}^B|. \quad (\text{SE43})$$

We observe that $\delta E_{0,j}$ is not constant but depends quite strongly on the value of the angular momentum j . This dependence can be rationalized by considering the Rashba SOC as a perturbation. As shown below, the spatial location of the zero modes is essentially determined by j . For $j = 0$ and $j \gg 1$, the radial wave function is localized far from the pn interface. In this case, the zero modes are supported on only one of the sublattices, so the Rashba

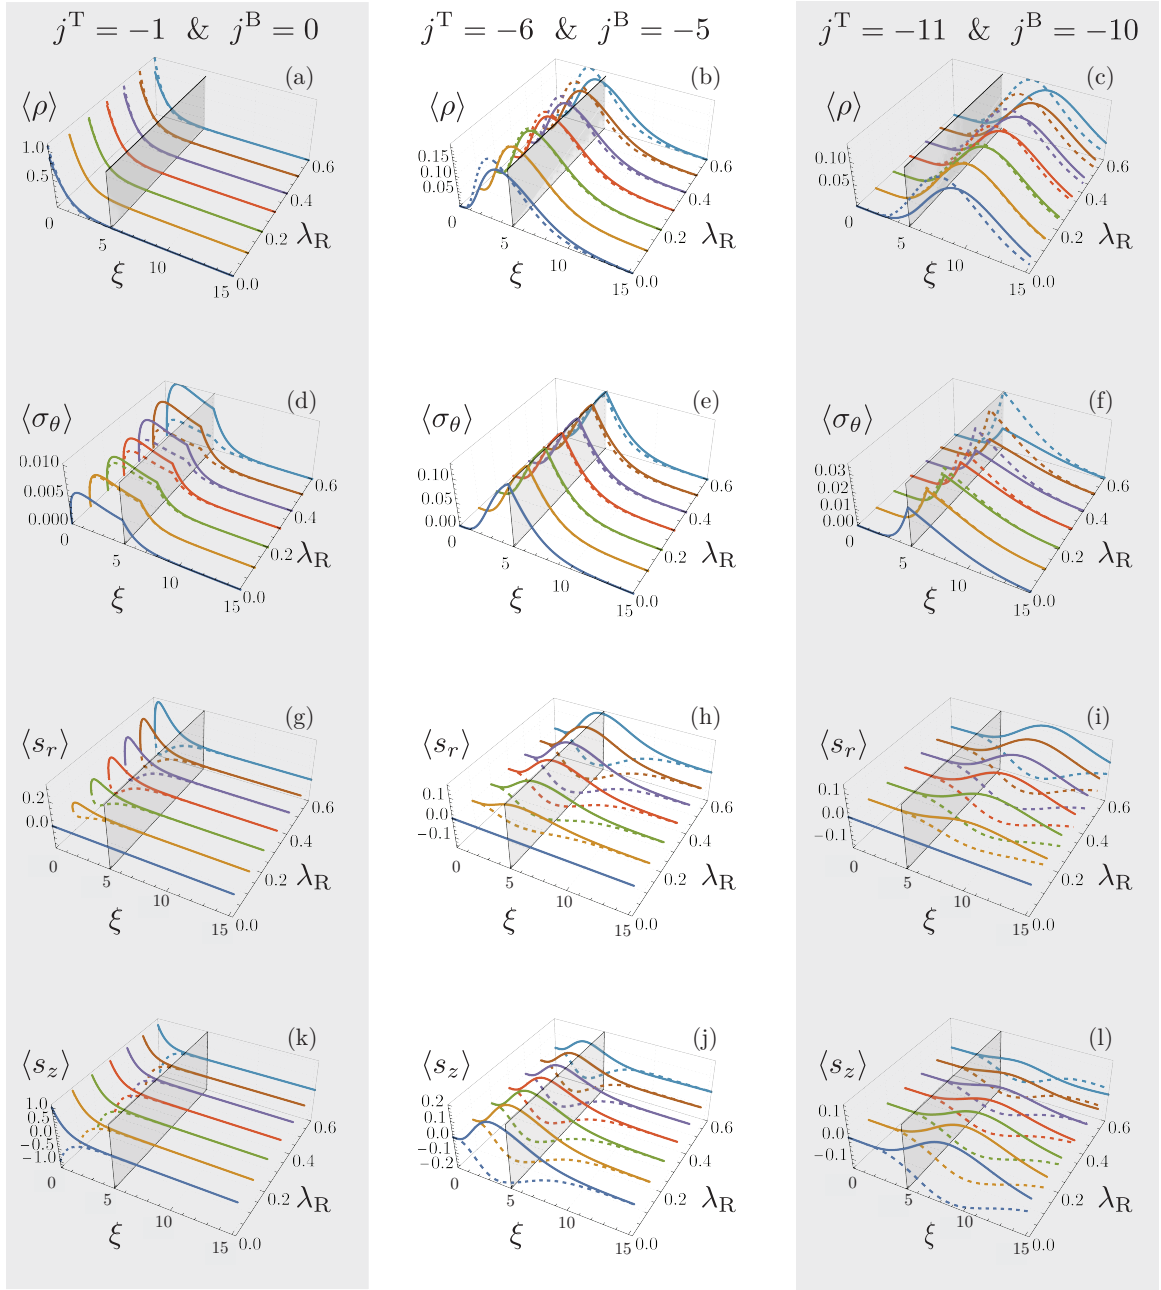

Figure SF4. Radial profile of the observable densities defined in Eq. (SE44) for the bottom (solid lines) and top (dashed lines) zero modes as a function of ξ for different values of the Rashba SOC λ_R ($\lambda_R = 0, 0.1, 0.2, 0.3, 0.4, 0.5, 0.6$). Panels (a) to (c) display the modulus square of the wave function for the lowest value of j ($j = -1/0$ for top/bottom mode), an intermediate value of j ($j = -6/-5$ for top/bottom mode), and a large value of j ($j = -11/-10$ for top/bottom mode). Panels (d) to (f), (g) to (i), and (k) to (l) are the same but for the densities $\langle \sigma_\theta \rangle$, $\langle s_r \rangle$, and $\langle s_z \rangle$ respectively. In all panels, the plane at $\xi_0 = 5.1$ represents the position of the *pn* interface.

SOC matrix element is very small. For values of j at which the wave function is localized close to the *pn* interface, instead, the zero modes have support on both sublattices so that the matrix element of the Rashba SOC is largest and the splitting reaches a maximum. A similar effect was observed in the case of the linear *pn* junction [53].

In the panels of Fig. SF4, we present the radial profiles of various observable densities for the top and bottom zero modes for several values of the Rashba SOC and for three different values of the angular momentum j . We denote these quantities as follows:

$$\langle \rho \rangle = \psi_j^{i\dagger} \psi_j^i, \quad \langle \sigma_\theta \rangle = \psi_j^{i\dagger} \sigma_\theta \psi_j^i, \quad \langle s_z \rangle = \psi_j^{i\dagger} s_z \psi_j^i, \quad \langle s_r \rangle = \psi_j^{i\dagger} s_r \psi_j^i, \quad i = T, B. \quad (\text{SE44})$$

They describe the radial probability density, the azimuthal probability current density, and the perpendicular and radial components of the spin density. (See Eqs. (SE46) and (SE46b) for the definition of σ_θ and s_r .) Because of symmetry, the two densities $\langle\sigma_r\rangle$ and $\langle s_\theta\rangle$ are identically zero. Panels (a) to (c) in Fig. SF4 clearly show how the radial profile of the probability density changes with the angular momentum j : the wave function is localized at the center of the circular region for $\{j^T, j^B\} = \{-1, 0\}$, it is located close to the pn interface for $\{j^T, j^B\} = \{-6, -5\}$, and finally, it moves outside the circular region and away from the pn interface for $\{j^T, j^B\} = \{-11, -10\}$. A similar behavior is found in all the other observables we have considered. We note that in the absence of Rashba SOC, the radial spin density $\langle s_r\rangle$ vanishes, and it increases for increasing values of λ_R . On the contrary, the perpendicular spin density $\langle s_z\rangle$ is finite also in the absence of Rashba SOC and decreases with increasing λ_R . This can be understood since for increasing λ_R the spin will tend to align with the effective magnetic field generated by the Rashba SOC [46].

V. EFFECTIVE ZERO-MODE HAMILTONIAN

In this section, we provide the details of the derivation of the effective one-dimensional (1D) Hamiltonian governing the spin and angular dynamics of the zero modes localized at the junction. We assume that the Fermi energy is at the charge neutrality point, $E_F = 0$, and we aim at an effective model valid in the low-energy region around E_F . We follow the approach of [54], where the effective 1D Hamiltonian for the analogous problem of electrons in a mesoscopic ring in the presence of Rashba SOC was derived. The approach is based on the projection of the full Hamiltonian onto the zero-energy radial state, localized at the interface between the p and the n regions. This projection is justified as long as the separation between the zero modes and the first Landau level is much larger than any other relevant energy scale in the problem.

We start with the Dirac equation

$$\mathcal{H}\Psi = E\Psi,$$

where the Hamiltonian (SE1) in the symmetric gauge is expressed in polar coordinates as follows:

$$\mathcal{H} = \sigma_r(-i\partial_r) + \sigma_\theta\left(\frac{L_z}{r} + A_\theta\right) + V(r) + \Delta\sigma_z + \lambda_Z s_z + \lambda_{\text{KM}}\sigma_z s_z + \frac{\lambda_R}{2}(\sigma_r s_\theta - \sigma_\theta s_r), \quad (\text{SE45})$$

with $A_\theta = r/2$, $V(r) = V_0 \text{sign}(R - r)$, $L_z = -i\partial_\theta$, and we have defined

$$\sigma_r = \cos\theta\sigma_x + \sin\theta\sigma_y = \begin{pmatrix} 0 & e^{-i\theta} \\ e^{i\theta} & 0 \end{pmatrix}, \quad (\text{SE46a})$$

$$\sigma_\theta = -\sin\theta\sigma_x + \cos\theta\sigma_y = \begin{pmatrix} 0 & -ie^{-i\theta} \\ ie^{i\theta} & 0 \end{pmatrix}, \quad (\text{SE46b})$$

with analogous expressions for s_r and s_θ . First, we make a unitary transformation in sublattice and spin space:

$$\tilde{\mathcal{H}} = U\mathcal{H}U^{-1}, \quad (\text{SE47a})$$

$$\tilde{\Psi} = U\Psi, \quad (\text{SE47b})$$

where $U = e^{i\frac{\sigma_z}{2}(\theta + \frac{\pi}{2})}e^{i\frac{s_z}{2}\theta}$. The additional $\pi/2$ rotation in sublattice space is included in order to obtain a real Hamiltonian. Using

$$U\sigma_r U^{-1} = -\sigma_y, \quad U\sigma_\theta U^{-1} = \sigma_x, \quad (\text{SE48})$$

$$Us_r U^{-1} = s_x, \quad Us_\theta U^{-1} = s_y, \quad (\text{SE49})$$

$$UL_z U^{-1} = L_z - \frac{\sigma_z}{2} - \frac{s_z}{2}, \quad (\text{SE50})$$

we arrive at

$$\tilde{\mathcal{H}} = i\sigma_y\left(\partial_r + \frac{1}{2r}\right) + \sigma_x\left(\frac{L_z}{r} + \frac{r}{2} - \frac{s_z}{2r}\right) + V(r) + \Delta\sigma_z + \lambda_Z s_z + \lambda_{\text{KM}}\sigma_z s_z - \frac{\lambda_R}{2}(\sigma_y s_y + \sigma_x s_x). \quad (\text{SE51})$$

Note that under the unitary transformation U , the total angular momentum J is mapped to $UJU^{-1} = L_z$. Next, we separate the Hamiltonian into a radial part and an angular/spin part, $\tilde{\mathcal{H}} = \tilde{\mathcal{H}}_r + \tilde{\mathcal{H}}_\theta$, where the radial part is defined as

$$\tilde{\mathcal{H}}_r = i\sigma_y\left(\partial_r + \frac{1}{2r}\right) + \frac{\sigma_x}{r}\left(\frac{r^2}{2} - \Phi\right) + V(r) + \Delta\sigma_z, \quad (\text{SE52})$$

and the angular/spin part as

$$\tilde{\mathcal{H}}_\theta = \frac{\sigma_x}{r}(L_z + \Phi) + \left(\lambda_Z + \lambda_{\text{KM}}\sigma_z - \frac{\sigma_x}{2r}\right)s_z - \frac{\lambda_R}{2}(\sigma_y s_y + \sigma_x s_x). \quad (\text{SE53})$$

Here, Φ is a parameter whose value is set in such a way that the zero mode of $\tilde{\mathcal{H}}_r$ is at the Fermi energy $E_F = 0$. In practice, Φ is with good approximation the magnetic flux through the pn junction in units of the flux quantum, $\Phi \approx R^2/2\ell_B^2$. The radial Hamiltonian $\tilde{\mathcal{H}}_r$ coincides, up to the $\pi/2$ rotation in sublattice space, with the model of a circular pn junction for spinless graphene solved in [22, 52], with the appropriate identification of the parameter Φ .

We now project the full Hamiltonian onto the spin-degenerate zero mode of $\tilde{\mathcal{H}}_r$. To this aim, we write the wave function as

$$\tilde{\Psi}(r, \theta) = \tilde{\psi}_0(r)\tilde{\chi}(\theta), \quad (\text{SE54})$$

where the sublattice spinor $\tilde{\psi}_0(r)$ is the zero mode of $\tilde{\mathcal{H}}_r$, which satisfies

$$\tilde{\mathcal{H}}_r \tilde{\psi}_0(r) = 0, \quad (\text{SE55})$$

and we choose to be real, and $\tilde{\chi}(\theta)$ is a two-component angular spinor in spin space. From the equation $\tilde{\mathcal{H}}\tilde{\Psi} = E\tilde{\Psi}$ we find that $\tilde{\chi}(\theta)$ satisfies the equation

$$\tilde{\mathcal{H}}_{\text{eff}}\tilde{\chi}(\theta) = E\tilde{\chi}(\theta), \quad (\text{SE56})$$

with the effective 1D Hamiltonian

$$\tilde{\mathcal{H}}_{\text{eff}} = \langle \tilde{\mathcal{H}} \rangle_0 = \omega_0(L_z + \Phi) + \left(\omega_Z - \frac{\omega_0}{2}\right)s_z - \omega_R s_x. \quad (\text{SE57})$$

Here, the brackets $\langle \dots \rangle_0$ denote the expectation value in the radial zero mode:

$$\langle \dots \rangle_0 = \int_0^\infty r dr \tilde{\psi}_0^\dagger(r) \dots \tilde{\psi}_0(r),$$

and we have used $\langle \sigma_y \rangle_0 = 0$, which holds because $\tilde{\psi}_0(r)$ is a real spinor. In Eq. (SE57) we have defined the angular velocity ω_0 and the Zeeman and Rashba frequencies ω_Z and ω_R , as follows:

$$\omega_0 \equiv \left\langle \frac{\sigma_x}{r} \right\rangle_0, \quad \omega_Z \equiv \lambda_Z + \lambda_{\text{KM}}\langle \sigma_z \rangle_0, \quad \omega_R \equiv \frac{\lambda_R}{2}\langle \sigma_x \rangle_0. \quad (\text{SE58})$$

Since σ_x before the unitary transformation was σ_θ , see Eq. (SE48), we recognize the coefficient of L_z , $\langle \sigma_x/r \rangle_0$, as the angular velocity of the circular motion along the junction, and the coefficient that renormalizes λ_R , $\langle \sigma_x \rangle_0$, as the azimuthal component of the velocity. Similarly, the vanishing of $\langle \sigma_y \rangle_0$ expresses the vanishing of the radial velocity. We note that if we undo the unitary transformation in spin space, we obtain the effective Hamiltonian

$$\mathcal{H}_{\text{eff}} = \omega_0(L_z + \Phi) + \omega_Z s_z - \omega_R s_r, \quad (\text{SE59})$$

which explicitly shows that the Rashba SOC acts as an effective magnetic field that pushes the spin in the in-plane radial direction.

It is straightforward to diagonalize $\tilde{\mathcal{H}}_{\text{eff}}$. Its eigenvalues read

$$E_{0,m,\pm} = \omega_0(m + \Phi) \pm \sqrt{\left(\omega_Z - \frac{\omega_0}{2}\right)^2 + \omega_R^2}, \quad (\text{SE60})$$

where m is an integer if we impose periodic boundary conditions. The corresponding eigenstates are

$$\tilde{\chi}_{m,+}(\theta) = \frac{e^{im\theta}}{\sqrt{2\pi}} \begin{pmatrix} \cos \frac{\gamma}{2} \\ -\sin \frac{\gamma}{2} \end{pmatrix}, \quad \tilde{\chi}_{m,-}(\theta) = \frac{e^{im\theta}}{\sqrt{2\pi}} \begin{pmatrix} \sin \frac{\gamma}{2} \\ \cos \frac{\gamma}{2} \end{pmatrix}, \quad (\text{SE61})$$

where we define

$$\sin \gamma = \frac{\omega_R}{\sqrt{(\omega_Z - \frac{\omega_0}{2})^2 + \omega_R^2}}, \quad \cos \gamma = \frac{\omega_Z - \omega_0/2}{\sqrt{(\omega_Z - \frac{\omega_0}{2})^2 + \omega_R^2}}. \quad (\text{SE62})$$

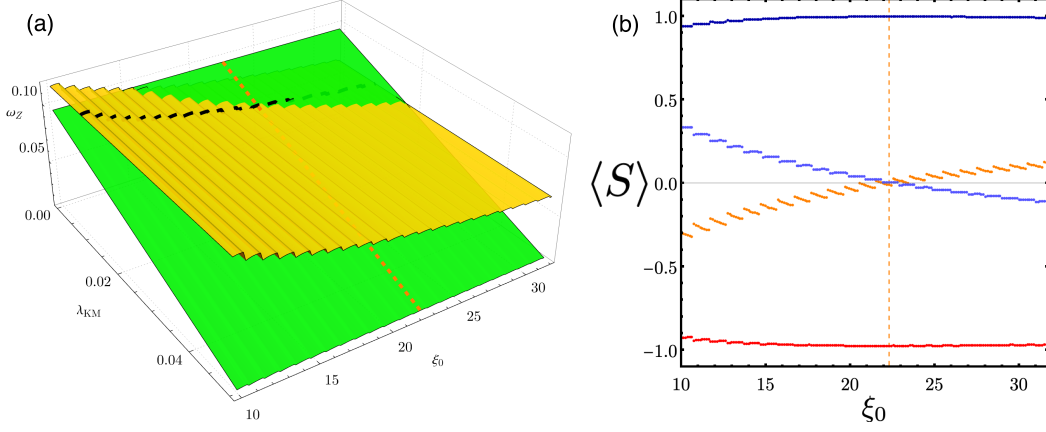

Figure SF5. (a) The angular frequency ω_0 in Eq. (SE58) (yellow plane) and the effective Zeeman frequency given by Eq. (SE63) (green plane) as functions of junction size ξ_0 and the Kane-Mele SOC λ_{KM} . The intersection of the green and yellow planes corresponds to the sweet spots where the resonance condition occurs. For a given value of λ_{KM} ($\lambda_{KM} = 0.01$ in the figure), illustrated by the black dashed line, the value of ξ_0 at which the resonance occurs is indicated by the red dashed line. (b) The exact expectation values of the radial and perpendicular spin components in the top and bottom modes as a function of ξ_0 , for $\lambda_Z = 0.048$ and $\lambda_R = 0.2$ and $\lambda_{KM} = 0.01$. The top curve shows $\langle s_r \rangle_B$, the bottom one $\langle s_r \rangle_T$, and the two central ones $\langle s_z \rangle_T$ and $\langle s_z \rangle_B$. In all the panels, $V_0 = 0.51$.

Equations (SE60) and (SE61) provide useful approximation to the SOC coupled zero-mode energies and wave functions, which hold as long as transitions to higher Landau levels due to $\tilde{\mathcal{H}}_\theta$ can be neglected, and for angular states with $m \approx -\Phi$, where it predicts a linear dependence of the energy on m .

We note that in the uniform system ($V_0 = 0$), the zero mode of $\tilde{\mathcal{H}}_r$ has only one non-vanishing sublattice amplitude (the sublattice pseudo-spin is down-polarized). As a consequence, both ω_0 and ω_R vanish, and the eigenstates are spin-polarized along the z direction and orbitally degenerate (i.e., the energy is independent of m). In the presence of the potential step ($V_0 \neq 0$), both sublattice amplitudes in $\tilde{\psi}_0$ are finite. Then ω_0 and ω_R are finite, the zero modes acquire a dispersion, and the Rashba term is activated and pushes the spin polarization in the planar radial direction. The spin dynamics is therefore controlled by the potential step amplitude V_0 .

VI. RABI CONDITION FOR GENERAL SPIN-ORBIT COUPLING

In the main text, we have investigated the Rabi condition for the full model in Eq. (SE1) under the assumption that only the Rashba SOC is non-vanishing, and that effects due to the VZSOC can be neglected — single-valley model. We now relax this condition and include the Kane-Mele (λ_{KM}) SOC terms. In general, the angular frequency associated with the Zeeman term can then be expressed as:

$$\omega_Z = \lambda_Z + \lambda_{KM} \langle \sigma_z \rangle_0. \quad (\text{SE63})$$

Notice that here the brackets $\langle \dots \rangle_0$ denote the expectation value in the j -state with energy closest to zero energy at the given value of ξ_0 . As already mentioned in the main text, in the single-valley approximation, the valley-Zeeman SOC just produces a shift of the Zeeman term. The Kane-Mele SOC gives a nontrivial contribution to ω_Z that depends on the expectation value of σ_z over the spinless system. In Fig. SF5, we present the effect of the Kane-Mele SOC on the shift of the Rabi condition. From Fig. SF5(a), we observe for fixed λ_Z that the position of the sweet spot ξ_0 for increasing values of λ_{KM} moves at larger values of the radius.

VII. S-MATRIX APPROACH

Here we introduce the scattering approach [59] used to obtain the quantum transmission and conductance of the interferometers discussed in the main text. We begin by discussing a spinless model and then generalize it to the spin-dependent case. Without any significant loss of generality, we stick to the p -dot-based interferometer depicted in Fig. SF6(a).

Incoming and outgoing chiral modes are described in Fig. [SF6](#) by fermionic annihilation operators $\{a_1, a_3\}$ and $\{b_1, b_3\}$, respectively, such that

$$\begin{pmatrix} b_1 \\ b_3 \end{pmatrix} = \begin{pmatrix} r & t' \\ t & r' \end{pmatrix} \begin{pmatrix} a_1 \\ a_3 \end{pmatrix}. \quad (\text{SE64})$$

The conductances G_{21} and G_{31} are determined from the scattering amplitudes r and t , respectively, by following the Landauer-Büttiker approach.

The scattering matrix on the r.h.s. of Eq. [\(SE64\)](#) can be obtained by combining the scattering blocks S_1 and S_2 corresponding to the barriers τ_1 and τ_2 , as depicted in Fig. [SF6\(b\)](#). These block are connected by channels $\{a_2, b_2\}$ propagating around the central p dot by accumulating additional phases ϕ_{\pm} , satisfying

$$\begin{pmatrix} b_1 \\ b_2 \end{pmatrix} = \begin{pmatrix} r_1 & t'_1 \\ t_1 & r'_1 \end{pmatrix} \begin{pmatrix} a_1 \\ a_2 \end{pmatrix}, \quad (\text{SE65})$$

$$\begin{pmatrix} a_2 \\ b_3 \end{pmatrix} = \begin{pmatrix} r_2 & t'_2 \\ t_2 & r'_2 \end{pmatrix} \begin{pmatrix} b_2 \\ a_3 \end{pmatrix}, \quad (\text{SE66})$$

with

$$\begin{aligned} r_1 &= \sqrt{1 - \tau_1}, & t'_1 &= e^{i\phi_-} \sqrt{\tau_1}, \\ t_1 &= e^{i\phi_+} \sqrt{\tau_1}, & r'_1 &= -e^{i(\phi_+ + \phi_-)} \sqrt{1 - \tau_1}, \\ r_2 &= \sqrt{1 - \tau_2}, & t'_2 &= \sqrt{\tau_2}, \\ t_2 &= \sqrt{\tau_2}, & r'_2 &= -\sqrt{1 - \tau_2}. \end{aligned}$$

After a little algebra, from [\(SE64\)](#)-[\(SE66\)](#) we find

$$r = r_1 + t'_1(1 - r_2 r'_1)^{-1} r_2 t_1, \quad (\text{SE67})$$

$$t = t_2(1 - r'_1 r_2)^{-1} t_1. \quad (\text{SE68})$$

Notice that expanding [\(SE67\)](#) and [\(SE68\)](#) as geometric series supplies the Feynman paths contributing to the quantum amplitudes due to multiple reflections between the barriers. Moreover, when the barriers are placed symmetrically on opposite sides of the dot we find that $\phi_+ = \phi_-$.

The results of Eqs. [\(SE67\)](#) and [\(SE68\)](#) can be generalized to the spin-dependent case by choosing convenient spin bases along the linear and circular pn junctions and calculating their local projection at barriers 1 and 2. For the circular junction, the natural choice is the spin-eigenstate basis, which evaluated at the barriers reads

$$|\chi_+, \ell\rangle = \begin{pmatrix} \cos \frac{\gamma}{2} \\ \ell \sin \frac{\gamma}{2} \end{pmatrix}, \quad (\text{SE69})$$

$$|\chi_-, \ell\rangle = \begin{pmatrix} \sin \frac{\gamma}{2} \\ -\ell \cos \frac{\gamma}{2} \end{pmatrix}, \quad (\text{SE70})$$

with $\ell = 1$ for barrier 1 and $\ell = -1$ for barrier 2. For linear junctions (acting as incoming and outgoing leads) we can simply choose the canonical z -basis

$$|\uparrow\rangle = \begin{pmatrix} 1 \\ 0 \end{pmatrix}, \quad |\downarrow\rangle = \begin{pmatrix} 0 \\ 1 \end{pmatrix}. \quad (\text{SE71})$$

The use of a field-dependent, spin-eigenstate basis has no practical advantage here since the conductance is independent of the spin phases gathered along the leads. As for the phases ϕ_{\pm} , they can be obtained by setting $E_{m,s} = 0$ in Eq. [\(SE60\)](#) and finding the corresponding spin-dependent m (which is not necessarily an integer any longer due to the open boundary conditions introduced by the barriers). As a result, we find

$$\phi^s = -s\pi \sqrt{\left(Q_Z - \frac{1}{2}\right)^2 + Q_R^2} - \pi\Phi, \quad s = \pm, \quad (\text{SE72})$$

with $Q_R = \omega_R/\omega_0$, $Q_Z = \omega_Z/\omega_0$, and where we have dropped the \pm subindex due to symmetry.

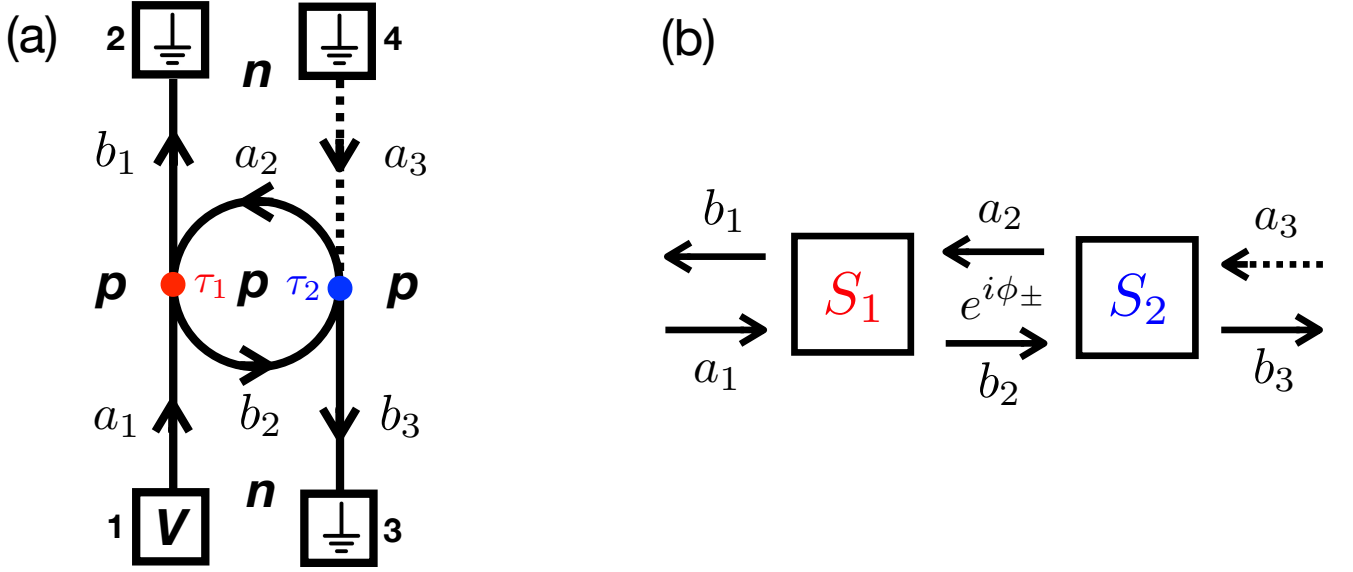

Figure SF6. (a) Sketch of the electronic circuit for the case of a p -doped circular region. We present the corresponding circuit for the n -doped circular region in the main text. (b) Generic representation of two scattering regions S_1 and S_2 separated by a region where the carriers can gain a geometrical phase $e^{i\phi_{\pm}}$.

The spin-dependent scattering amplitudes are determined by the projections $\langle \uparrow | \chi_s, \ell \rangle$ and $\langle \downarrow | \chi_s, \ell \rangle$, and by the phases (SE72), accordingly. In this way, we find

$$r_1 = \sqrt{1 - \tau_1} \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, \quad (\text{SE73})$$

$$t_1 = \sqrt{\tau_1} \begin{pmatrix} e^{i\phi^+} \cos \frac{\gamma}{2} & -e^{i\phi^+} \sin \frac{\gamma}{2} \\ e^{i\phi^-} \sin \frac{\gamma}{2} & e^{i\phi^-} \cos \frac{\gamma}{2} \end{pmatrix}, \quad (\text{SE74})$$

$$t'_1 = \sqrt{\tau_1} \begin{pmatrix} e^{i\phi^+} \cos \frac{\gamma}{2} & e^{i\phi^-} \sin \frac{\gamma}{2} \\ -e^{i\phi^+} \sin \frac{\gamma}{2} & e^{i\phi^-} \cos \frac{\gamma}{2} \end{pmatrix}, \quad (\text{SE75})$$

$$r'_1 = -\sqrt{1 - \tau_1} \begin{pmatrix} e^{i2\phi^+} & 0 \\ 0 & e^{i2\phi^-} \end{pmatrix}, \quad (\text{SE76})$$

$$t_2 = \sqrt{\tau_2} \begin{pmatrix} \cos \frac{\gamma}{2} & \sin \frac{\gamma}{2} \\ \sin \frac{\gamma}{2} & -\cos \frac{\gamma}{2} \end{pmatrix}, \quad (\text{SE77})$$

$$r_2 = \sqrt{1 - \tau_2} \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}. \quad (\text{SE78})$$

Here we omit the spin-dependent expressions for t'_2 and r'_2 since they do not contribute to the scattering amplitude matrices t and r in Eqs. (SE67) and (SE68). By following the Landauer-Büttiker approach, we find the expression for the linear conductances in terms of t and r that we use in the main text:

$$G_{21} = \frac{e^2}{h} \text{tr}[rr^\dagger], \quad (\text{SE79})$$

$$G_{31} = \frac{e^2}{h} \text{tr}[tt^\dagger]. \quad (\text{SE80})$$

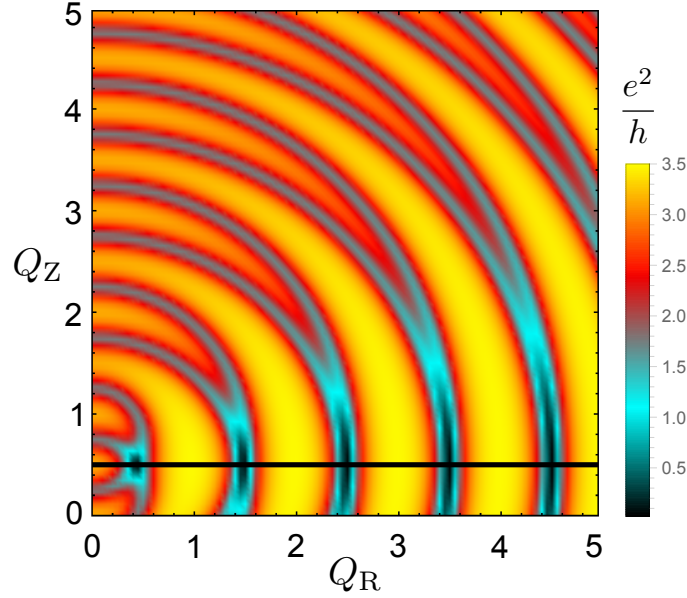

Figure SF7. Differential conductance $G_{21} = G_{21}^+ + G_{21}^-$ for the circuit of Fig. 3(b) including a valley-Zeeman $Q_{VZ} = 0.25$. The solid line at $Q_Z = 1/2$ corresponds to a symmetry axis in the pattern.

VIII. FIRST-ORDER EXPANSION

The scattering amplitudes (SE67) and (SE68) can be expanded as

$$r = r_1 + t'_1 r_2 t_1 + t'_1 r_2 r'_1 r_2 t_1 + \dots, \quad (\text{SE81})$$

$$t = t_2 t_1 + t_2 r'_1 r_2 t_1 + \dots \quad (\text{SE82})$$

These expansions have a simple interpretation in terms of Feynman paths: each term corresponds to a possible scattering history through barriers 1 and 2, comprising a different number of windings around the central dot. Previous works in semiconductor-based rings [46, 60] have shown that the first two terms in the expansions (SE81) and (SE82), corresponding to zero- and single-winding path contributions, are sufficient to capture all relevant features of the conductances (SE79) and (SE80). This also facilitates further physical insight by discriminating the role that different quantum phases play in the interference. By setting $\tau_1 = \tau_2 = 1/2$ and neglecting higher order contributions, we find

$$G_{21} \approx 1 + \cos \phi_{AB} \cos \phi_S, \quad (\text{SE83})$$

with

$$\phi_{AB} = 2\pi\Phi, \quad (\text{SE84})$$

$$\phi_S = 2\pi\sqrt{\left(Q_Z - \frac{1}{2}\right)^2 + Q_R^2}, \quad (\text{SE85})$$

where ϕ_{AB} and ϕ_S are independent phase contributions with origin in the orbital and spin degrees of freedom, respectively.

IX. EFFECTS OF VALLEY-ZEEMAN COUPLING

The introduction of the valley-Zeeman coupling leads to a valley-dependent shift in the Zeeman term (a valley splitting), such that $\lambda_Z \rightarrow \lambda_Z + \tau\lambda_{VZ}$, with $\tau = \pm 1$ the valley index. This implies that the sweet spots corresponding to in-plane spin eigenstates and π geometric phases shift as well, in a valley-dependent way. By assuming no valley mixing (due to the separation between lattice and pn -junction length scales), the conductance turns valley-dependent. The 1st order expansion of Sec. VIII generalizes to

$$G_{21}^\tau \approx 1 + \cos \phi_{AB} \cos \phi_S^\tau, \quad (\text{SE86})$$

with

$$\phi_S^\tau = 2\pi \sqrt{\left(Q_Z + \tau Q_{VZ} - \frac{1}{2}\right)^2 + Q_R^2}, \quad (\text{SE87})$$

and $Q_{VZ} = \lambda_{VZ}/\omega_0$. The valley-resolved conductances for circuits with n - and p -doped central regions would then look like those of Figs. 3(c) and 3(d) with additional $\pm Q_{VZ}$ shifts along the Q_Z axis, respectively. As for the total conductance, it is the sum of the corresponding valley conductances, $G_{21} = G_{21}^+ + G_{21}^-$. In Fig. **SF7** we illustrate this situation for the p -doped dot circuit of Fig. 3(b), with the same setting used to produce Fig. 3(d) and an additional valley-Zeeman coupling $Q_{VZ} = 0.25$. The composed pattern is symmetric with respect to the axis $Q_Z = 1/2$. Although this axis does not correspond any longer to a sweet spot in the strict sense discussed above, we notice that the average spin projection along z vanishes at $Q_Z = 1/2$, i.e., $\langle s_z \rangle = \langle s_z \rangle_+ + \langle s_z \rangle_- = 0$, due to the opposite valley-Zeeman pulls.
