Abstract

A large set of macroeconomic variables have been suggested as equity risk premium predictors in the literature. Acknowledging the different predictability of the equity premium in expansions and recessions, this paper proposes an approach that combines equity premium forecasts from two-state regression models using an agreement technical indicator as the observable state variable. A comprehensive out-of-sample forecast evaluation exercise based on statistical and economic loss functions demonstrates the superiority of the proposed approach versus combined forecasts from linear models or Markov switching models, and forecasts from machine learning methods such as random forests and gradient boosting. The parsimonious state-dependent aspect of the risk premium forecasts delivers large improvements in forecast accuracy. The results are robust to sub-period analyses and different investors' risk aversion levels.

1 Introduction

The predictability of the equity market return in excess of the risk-free interest rate plays an important role in several areas of finance such as asset pricing, asset allocation and risk management. The prolific equity premium prediction literature has established that a host of macroeconomic variables have in-sample predictive power for the equity premium; see, for instance, Fama and French (1988), Lettau and Ludvigson (2001), and Ang and Bekaert (2002, 2007). Several studies raised skepticism, however, about the predictability of the equity premium upon the empirical finding that the out-of-sample equity premium forecasts from regression models based on macroeconomic indicators are no better than the historical average benchmark; see, e.g., Bossaerts and Hillion (1999), Goyal and Welch (2003), Butler *et al.* (2005) and Welch and Goyal (2008).

A branch of the empirical finance literature has adduced evidence of out-of-sample equity premium predictability using additional predictors over and above macroeconomic variables such as technical indicators (Neely *et al.*, 2014), commodity risk factors (Fernandez-Perez *et al.*, 2017), liquidity and uncertainty predictors (Batten *et al.*, 2022), or alternative modelling approaches (Campbell and Thompson, 2008; Rapach *et al.*, 2010; Ferreira and Santa-Clara, 2011; Rapach and Zhou, 2013; Pettenuzzo *et al.*, 2014; Chicaroli and Valls Pereira, 2015; Ciner, 2022; Lima and Godeiro, 2023; Lu *et al.*, 2023). For a survey of the equity premium predictability literature see Goyal *et al.* (2023).

The present paper is concerned with forecast combination and within this framework we propose an parsimonious non-linear (state-dependent) approach to predict month-ahead the equity premium. It proceeds in two stages. At the first stage, we construct equity premium forecasts using different two-state regression models using one, two or three macroeconomic predictors only. The state variable in these models is observable and novel as defined by an agreement of several technical indicators. Using NBER recessions and expansions data, we underpin this choice of state variable by showing that (binary) technical indicators constructed from equity market prices and/or volume data up to month t are good real-time indicators of the business cycle (expansion versus recession) on month $t + 1$.¹ The goal is to accommodate expansion-versus-recession variation in the equity premium predictability in a parsimonious manner that exploits the information content of technical indicators. At stage two, we combine the forecasts from the individual two-state regression models using equal weights. We compare

¹The NBER business cycle indicator is precluded as observable state variable in our models since it is released with a lag because the NBER-dating committee waits long enough so that the existence of a peak or trough is not in doubt (see <http://www.nber.org/cycles/>). For instance, the Committee's determination of the peak date in December 2007 occurred 11 months after that date and that of the trough date of June 2009 occurred 15 months after that date.

these equity premium predictions with the likewise equal-weighted forecasts from *linear* regression models and from conventional Markov-switching models where the state variable is latent. We also consider diffusion indices, an alternative way of conditioning the equity premium forecasts on multiple macroeconomic variables by extracting a few principal components and using them as predictors in a regression. Furthermore, we acknowledge non-linearity in the predictability of the equity premium in a non-parametric manner by also generating forecasts from two machine learning methods: random forests and gradient boosting.

Our paper relates to a theoretical literature which argues that the equity risk premium predictability is not constant over time. The intertemporal capital asset pricing model (ICAPM) of Merton (1973) implies that cyclical risk aversion may induce time-variation in the degree of equity premium predictability. In line with rational asset pricing, the level of investors' risk aversion may differ during economic expansions and recessions (Cochrane, 2011) which, in turn, indicates that the predictive nexus between macroeconomic variables and the equity premium may be regime-sensitive.

Our findings speak to an empirical literature which suggests that there is time-variation in the equity risk premium predictability related to macroeconomic risk. Bali (2008) finds that relative risk aversion coefficients are not constant over time but differ notably over expansions and recessions. Various empirical studies document that equity returns follow a two-regime process; see, e.g., Turner *et al.* (1989), Garcia and Perron (1996), Perez-Quiros and Timmermann (2000), Ang and Bekaert (2002, 2007), Ang and Chen (2002), Guidolin and Timmermann (2006a,b), Timmermann (2006) and Pettenuzzo and Timmermann (2011). In the Bayesian framework proposed by Tu (2010) for portfolio decision-making, the certainty-equivalent losses associated with ignoring regime-switching from stock market upturns to downturns and vice versa are shown generally to exceed 2% per annum. Henkel *et al.* (2011), Dangl and Halling (2012), Gargano and Timmermann (2014) and Neely *et al.* (2014) find that most macroeconomic indicators emit stronger (more informative) signals about future equity premia in recessions than in expansions. Jacobsen *et al.* (2016) find that industrial metal returns are positive (negatively) related with future equity premia in recessions (expansions). However, the models employed in the equity premium predictability literature do not explicitly account for state-dependence. The exceptions are a few studies that forecast the equity premium with Markov-Switching models (Guidolin and Timmermann, 2007; Henkel *et al.*, 2011; Dangl and Halling, 2012; Zhu and Zhu, 2013). Our paper advocates an approach to predict the equity premium through novel, parsimonious threshold models where the state variable is observable as dictated by an agreement of technical

indicators.

Our study strengthens the equity premium prediction literature which advocates the combination of forecasts from parsimonious models as an efficient and effective way to blend the information from many macroeconomic predictors. Large-dimensional “kitchen sink” regression models can encounter heightened parameter estimation uncertainty due to near-collinear predictors and degrees-of-freedom constraints a low signal-to-noise ratio. This problem can be circumvented through the equal-weights combination of forecasts from single-predictor models (i.e., an individual macroeconomic predictor per model) which is the approach advocated by Rapach *et al.* (2010) and later extended by Elliott *et al.* (2013) to the combination of the complete-subset k -predictor regressions.² As argued by Rapach *et al.* (2010) the data-generating process of expected equity returns is highly uncertain, complex and constantly evolving; in this context, forecast combinations notably reduces the uncertainty/parameter instability risk associated with reliance on a single model. The equity premium forecast combination approaches deployed by Rapach *et al.* (2010) and Rapach and Zhou (2013) employ both equal-weights and weights based on the past forecasting performance of the individual models. Their findings strongly endorse the equal-weights combination.³

Section 2 presents the macroeconomic variables and technical indicators employed in our models as candidate predictors and state variables, respectively. Section 3 discusses the forecasting methods. Section 4 outlines the statistical and economic forecast evaluation criteria. Section 5 discusses the S&P 500 equity premium predictability findings, and Section 6 concludes.

2 Equity Premium Predictors: Data Description

Macroeconomic variables are theoretically motivated as equity premium predictors. The fundamental insight of the Merton (1973)’s ICAPM theory is that, in solving their lifetime consumption decisions under uncertainty, long-term investors care not only about the current level of their invested wealth but also about the future returns on that wealth. More formally, the ICAPM theory contends that in equilibrium the expected excess return on an asset is driven by its covariance with current returns on total invested wealth and with (macroeconomic) state variables that contain information about future

²For a given set of K predictors, the complete-subset regressions are all possible regressions with $k \leq K$ predictors.

³Close alternatives to the equal-weights combination are the median combination, where the forecast is $median\{\hat{r}_{i,t+1}\}$, $i = 1, \dots, N$, and the trimmed mean combination, which imposes $\omega_{i,t} = 0$ on the p smallest and p largest forecasts and uses weights $\omega_{i,t} = 1/(N - 2p)$ on the remaining individual forecasts. The latter is strictly-speaking not parameter-free as it requires the choice of p . Rapach *et al.* (2010) show that the equal-weight combined forecasts are not outperformed by the median and trimmed-mean combined forecasts either.

returns on invested wealth. The state of the economy is the key driver of time-varying expected stock returns; namely, heightened risk aversion during economic downturns requires a higher risk premium and generates equity premium predictability (Fama and French, 1989; Cochrane, 2011).

The macroeconomic variables entertained as equity premium predictors in our analysis are:

- (1) *Dividend yield (DY)*: logarithm of past 12-month sum of dividends to 1-month lagged price ratio.
- (2) *Earnings-price ratio (EP)*: log of past 12-month sum of earnings to current price.
- (3) *Dividend payout ratio (DE)*: log of past 12-month sum of dividends to sum of earnings.
- (4) *Equity premium realized volatility (RVOL)*: Mele (2007) estimator $RVOL_t = [\sqrt{6\pi}(|r_t| + \dots + |r_{t-11}|)]/12$.
- (5) *Book-to-market ratio (BM)*: book value over market value of DJIA index.
- (6) *Net equity expansion (NTIS)*: ratio of past 12-month sum of net issues by NYSE listed stocks to end-of-year market capitalisation.
- (7) *Treasury bill (TBL)*: 3-month U.S. Treasury bill rate.
- (8) *Long-term rate of returns (LTR)*: return on long-term U.S. government bonds.
- (9) *Term Spread (TMS)*: long-term government bond yield minus Treasury bill rate.
- (10) *Default yield spread (DFY)*: difference in Moody's BAA and AAA rated corporate bond yields.
- (11) *Default return spread (DFR)*: long-term corporate bond return minus LTR.
- (12) *Inflation (INFL)*: change in the logarithmic consumer price index (CPI).

Technical indicators are binary variables constructed primarily from historical equity market prices. In a recent paper, Neely *et al.* (2014) probe that technical indicators have additional predictive information for the equity premium over and above macroeconomic variables. The intuition is that technical indicators are able to signal changes in investor sentiment which are known to correlate with future stock returns, as borne out by the evidence in Neely *et al.* (2014). Following this wisdom, we entertain the same set of 14 trend-following type technical indicators as Neely *et al.* (2014). Six of these technical indicators belong to the *moving average* MA(a,b) family

$$MA_t(a, b) = \begin{cases} 1 & \text{if } (\sum_{j=0}^{a-1} P_{t-j})/a \leq (\sum_{i=0}^{b-1} P_{t-i})/b, \\ 0 & \text{if } (\sum_{j=0}^{a-1} P_{t-j})/a > (\sum_{i=0}^{b-1} P_{t-i})/b, \end{cases} \quad (1)$$

where P_t is the month t level of the S&P 500 index; we consider $a = 1, 2, 3$ and $b = 9, 12$ months.

Two other technical indicators also based solely on equity prices belong to the *momentum* family

$$\text{MOM}_t(l) = \begin{cases} 1 & \text{if } P_t > P_{t-l}, \\ 0 & \text{if } P_t \leq P_{t-l}, \end{cases} \quad (2)$$

with $l = 9, 12$ months. The final six technical indicators belong to a family that uses volume data

$$\text{VOL}_t(a, b) = \begin{cases} 1 & \text{if } (\sum_{j=0}^{a-1} \text{OBV}_{t-j})/a \leq (\sum_{j=0}^{b-1} \text{OBV}_{t-j})/b, \\ 0 & \text{if } (\sum_{j=0}^{a-1} \text{OBV}_{t-j})/a > (\sum_{j=0}^{b-1} \text{OBV}_{t-j})/b, \end{cases} \quad (3)$$

where $\text{OBV}_t = \sum_{i=1}^t \text{Vol}_i \times D_i$ is the *on-balance volume* with Vol_i denoting the volume traded in the S&P 500 index on month i and D_i denoting a directional indicator that takes value 1 if $P_i - P_{i-1} \geq 0$ and -1 if $P_i - P_{i-1} < 0$. As in Neely *et al.* (2014), we compute signals for $a = 1, 2, 3$ and $b = 9, 12$.

We depart from Neely *et al.* (2014) in (a) defining an *agreement technical indicator* that blends all 14 technical indicators, (b) utilising the agreement indicator as observable state variable in parsimonious threshold models of the equity premium. The p th agreement technical indicator is defined as

$$A_{p,t} = \mathcal{I}\left(\sum_{i=1}^{14} \text{TECH}_{i,t} \geq p\right), \quad (4)$$

where $\text{TECH}_{i,t}$ are the technical indicators presented in Section 2, $p \in \{1, \dots, 14\}$, and $\mathcal{I}(\text{condition})$ is equal to one if the condition is met, and zero otherwise.

Our empirical analysis is based on monthly data from December 1950 to December 2017 for the S&P500 index and the above 12 macroeconomic variables and 14 technical indicators. The equity risk premium is given by the logarithmic difference between the return on the S&P500 (including dividends) and the Treasury-bill rate. The data source is Amit Goyal's webpage <http://www.hec.unil.ch/agoyal/>.

3 Forecasting Methodology

Let r_{t+1} denote the equity premium defined as the return on a broad stock market index, including dividends, in excess of the risk-free interest rate from the month t to month $t + 1$, and $x_{i,t}$ the month t value of the i th macroeconomic predictor, $i = 1, \dots, N$. At month t we want to predict r_{t+1} based on the observations from the return and predictors from month 1 to t . The forecasting approaches entertained in the paper are described next.

3.1 Linear model forecasts

The simplest predictive model for the equity risk premium is the single-predictor linear regression

$$r_{t+1} = \alpha_i + \beta_i x_{i,t} + \varepsilon_{i,t+1}, t = 1, \dots, T, (5)$$

where $x_{i,t}$ is each of our candidate macroeconomic variables and $\varepsilon_{i,t+1}$ is the error term.

Let $E_t(\cdot)$ denote the conditional expectation based on the information available at time t . A forecast of the OOS equity premium, $E_t(r_{t+1})$, can be constructed from model (5) as $\hat{r}_{t+1} = \hat{\alpha}_i + \hat{\beta}_i x_{i,t}$, where $(\hat{\alpha}_i, \hat{\beta}_i)$ are parameter estimates based on data up to time t . By assuming no-predictability or that $x_{i,t}$ has no predictive ability (imposing $\beta_i = 0$), the constant expected equity premium model arises; accordingly, the month-ahead forecast is the historical average (HA) of excess returns, i.e., $\bar{r}_{t+1} = (\sum_{i=1}^t r_i)/t$. If $x_{i,t}$ conveys information about the future equity risk premium, then \hat{r}_{t+1} should outperform the no-predictability HA benchmark.

A natural extension of model (5) is the k -predictor LIN model. There are $\binom{N}{k}$ candidate models in the complete-subset LIN(k) family of models where N is the number of macroeconomic predictors available.⁴ Formally, the different LIN($k=2$; two-regressor) models can be written as

$$r_{t+1} = \alpha_{ij} + \beta_i x_{i,t} + \beta_j x_{j,t} + \varepsilon_{ij,t+1}, (6)$$

where $i, j = 1, \dots, N (i \neq j)$. Elliott *et al.* (2013) demonstrate that the quality of the OOS complete-subset combined forecasts can quickly deteriorate as k increases. Given the high dependence among macroeconomic predictors, we consider complete-subset LIN models with $k = \{1, 2, 3\}$.

3.2 non-linear two-state model forecasts

Rapach *et al.* (2010) and Rapach and Zhou (2013) show that simple linear regressions using macroeconomic predictors and equal-weighted (EW) combinations thereof, respectively, produce larger out-of-sample (OOS) forecast accuracy gains versus the historical average benchmark in recessions than in expansions.⁵ We consider an extension of model (5) to accommodate a specific type of non-linear

⁴The combination number $\binom{N}{k}$ gives the total number of ways to combine N numbers in groups of k . Elliott *et al.* (2013) average the forecasts across complete-subset regressions, that is, all possible regressions with $k \leq N$ predictors where N is the total number of candidate predictors.

⁵Other studies showing that the predictability of the equity premium is greater in recessions are Henkel *et al.* (2011), Dangl and Halling (2012), Rapach and Zhou (2013), Gargano and Timmermann (2014) and Neely *et al.* (2014) inter alia.

predictability, state-dependence, where the state variable is defined as an observable.

The two-state regression (TSR) model for the single macroeconomic variable $x_{i,t}$ can be written as

$$r_{t+1} = \alpha_{i0} + \alpha_{i1}A_{p,t} + \beta_{i0}x_{i,t} + \beta_{i1}A_{p,t}x_{i,t} + \varepsilon_{t+1}. \quad (7)$$

where the state variable $A_{p,t}$ is one of the 14 agreement technical indicators ($A_{k,t}$, $k = 1, \dots, 14$ defined in (4)). As in the LIN models we consider the complete-subset TSR models with $k = \{1, 2, 3\}$ ⁶. For each estimation window and state-dependent model we select the agreement indicator which minimises the in-sample mean square adjustment error. In our empirical analysis, we also consider a version of the TSR model where only the coefficients of the explanatory variables depend on the state variable, not the intercept.

3.3 non-linear Markov-switching model forecasts

The Markov-switching (MS) extension of the linear predictive model (5) relies on a latent state variable, S_t , that is assumed to follow an order-one Markov chain with transition matrix

$$\mathbf{\Pi} = \begin{pmatrix} p_{11} & 1 - p_{11} \\ 1 - p_{22} & p_{22} \end{pmatrix}, \quad (8)$$

where the element p_{ij} denotes the probability of switching from state i on month t to state j on month $t + 1$ (Guidolin and Timmermann, 2007; Chauvet and Piger, 2008; Henkel *et al.*, 2011; Dangl and Halling, 2012; Zhu and Zhu, 2013). We consider the following MS generalization of the LIN($k=1$) model

$$r_{t+1} = \alpha_{i,S_t} + \beta_{i,S_t}x_{i,t} + \varepsilon_{i,t+1}, \quad (9)$$

where α_{i,S_t} and β_{i,S_t} are the predictive intercept and slope, respectively, at state S_t . Again We consider two cases: with the equal intercept ($\alpha_{i,1} = \alpha_{i,2}$). restriction and without it. As with the previous two modelling classes (LIN and non-linear TSR), for the MS class of non-linear models we also generate forecasts from the complete-subset $k = \{1, 2, 3\}$ specifications.⁷

Using the Perlin (2014)'s MATLAB code, which we gratefully acknowledge, we estimate the MS

⁶Since we have 12 macroeconomic variables we have 12,66 and 220 models with one, two and three regressors, respectively.

⁷Using the MS regr MATLAB package, we estimate the MS models by maximum likelihood via the Hamilton's filter to construct the unobserved transition matrix $\mathbf{\Pi}$.

models by maximum likelihood using the Hamilton’s filter to obtain the unobserved transition matrix Π .

3.4 Combined forecasts

For each family of models – either LIN regression models, TSR models, or MS models – we have a total number $S \equiv \binom{N}{k}$ of forecasts available for combination (where N is the number of available macroeconomic predictors) which are obtained by recursive estimation of the S complete-subset regressions associated. For instance, $k = 1$ represents the simple (single-predictor) case, $k = 2$ the two-predictor case and so forth.

Let $\hat{r}_{i,t+1}$ denote the equity premium forecast obtained from the i th model, $i = 1, \dots, S$. The mean of all S forecasts is usually referred to as the EW forecast combination

$$\hat{r}_{t+1}^{EW} = \sum_{i=1}^S \omega_{i,t} \hat{r}_{i,t+1} = \sum_{i=1}^S \frac{1}{S} \hat{r}_{i,t+1} = \text{mean}\{\hat{r}_{i,t+1}\}, \quad (10)$$

which represents the simplest (parameter-free) combination approach. We use the notation EW-LIN(k=j) to refer to the equity premium prediction obtained as the equal-weighted (EW) combination of S forecasts from linear models with j predictors; similar notation is used for the non-linear model combinations of the preceding two subsections as EW-TSR(k=j) and EW-MS(k=j), respectively.

3.5 Machine learning forecasts

We generate equity premium forecasts from two popular ensemble models based on decision trees for regression, gradient boosting (GB) and random forest (RF), that accommodate general forms of non-linearity. The GB approach, proposed by Friedman (2001), builds many trees in a gradual, additive and sequential manner, so that the trees are fitted one at a time, where each new tree helps to correct errors made by previously trained tree. This procedure is aimed at reducing the forecast bias and variance of a single tree and generalises boosting methods by allowing optimisation of an arbitrary differentiable loss function.

The RF is constructed by fitting multiple decision trees at training time and outputting the mean prediction of the individual trees. The algorithm for random forests applies the technique of bootstrap aggregating, or bagging, to tree learners. Given a training set $X = \mathbf{x}_1, \dots, \mathbf{x}_n$ with responses $Y = y_1, \dots, y_n$, bagging repeatedly (B times) selects a random sample with replacement of the training set

and fits trees to these samples. In each of $b = 1, \dots, B$: iterations (training) the bagging proceeds as follows

1. Sample, with replacement, n training examples from X, Y ; call these X_b, Y_b .
2. Train a modified regression tree f_b on X_b, Y_b , which is a tree learning algorithm that selects, at each candidate split in the learning process, a random subset of the features. This process is sometimes called "feature bagging".

After training, predictions for unseen samples can be made by averaging the predictions from all the individual regression trees on X as $\hat{f} = B^{-1} \sum_{b=1}^B f_b(X)$. The bootstrapping procedure improves the forecast performance, i.e., the mean square prediction error by decreasing the forecast variance without increasing the bias. If some features are very strong predictors for the response variable, these features will be selected in several of the B trees, which will become strongly correlated. The motivation for "feature bagging" is to mitigate the correlation of the individual trees in the bootstrap sample⁸.

4 Out-of-sample forecast evaluation tools

This section describes the methods used in the paper to evaluate the J one-month-ahead OOS forecasts obtained sequentially through expanding estimation windows.

4.1 Statistical criteria

The first statistical criterion, introduced by Campbell and Thompson (2008), measures the reduction in the mean squared error (MSE) of a specific model-based forecasting approach versus the HA benchmark

$$R_{OOS}^2 = 1 - \frac{\sum_{j=0}^{J-1} (\hat{r}_{t+j+1} - r_{t+j+1})^2}{\sum_{j=0}^{J-1} (\bar{r}_{t+j+1} - r_{t+j+1})^2}, \quad (11)$$

where J is the number of OOS months, \hat{r}_{t+j+1} is the OOS forecast for month $t + j + 1$ based on the estimation window starting on month 1 and ending on month $t + j$ and \bar{r}_{t+j+1} is the HA in the same estimation window. We report the above R_{OOS}^2 statistic based on the OOS forecasts associated to all J recursive estimation windows (months $t + 1$ to $t + J$), and two additional measures computed, separately, on the expansionary (Exp) and recessionary (Rec) months according to the NBER-cycle

⁸We deploy the RF and GB decision trees with the *sklearn* package from Python. The RF hyper-parameters considered in our application are the number of trees (or n-estimators) set at 100, 200 and 400 and the number of features to consider when looking for the best split (max features) at 2 and 4, while the other hyper-parameters are left at the default values. The GB hyper-parameters used are the number of trees (n-estimators) again at 100, 200, and 400 and the learning rate at 0.1 and 0.01, while the other hyper-parameters are left at the default values.

dating. We also report an R_{OOS}^2 measure that uses instead the Rapach *et al.* (2010) simple average of forecasts from simple LIN($k=1$) models, denoted EW-LIN($k=1$) in Section 3.1, as the benchmark.

Next we formally test the null hypothesis that the benchmark, HA or EW-LIN($k=1$), has at least as good predictive content for the month-ahead equity premium as the model-based forecast at hand; i.e. $H_0: R_{OOS}^2 \leq 0$ against $H_A: R_{OOS}^2 > 0$. For this purpose, we utilise the Clark and West (2007) test which is based on the MSE-adjusted statistic and can be cast as an extension of the Diebold and Mariano (1995) and West (1996) tests that allows comparisons between nested models.⁹

Because the R_{OOS}^2 (and associated tests) is an overall measure of forecast performance based on the mean prediction error, a point statistic, it can mask important instability in forecast performance. To gauge the dynamics of the forecast performance over the OOS months, in the third analysis, we plot the differential Cumulative Square Error (CSE), given by

$$\Delta CSE_j = \sum_{s=0}^j \{(\bar{r}_{t+s+1} - r_{t+s+1})^2 - (\hat{r}_{t+s+1} - r_{t+s+1})^2\}, \quad (12)$$

against j , such that a positively (negatively)-sloped ΔCSE_t graph indicates that the forecasting model at hand consistently outperforms (underperforms) the HA benchmark; a switch from a positive to a negative slope or vice versa indicates unstable forecast performance. We also define a ΔCSE_j variant based on the EW-LIN($k = 1$) forecasting approach of Rapach *et al.* (2010) as the relevant benchmark.

4.2 Economic criteria

We carry out an asset allocation exercise to compare the economic merit of the equity premium forecasts. Our representative investor forms a portfolio at time t by allocating ω_t of her total wealth to stocks and the remainder $(1 - \omega_t)$ to risk-free bills. Accordingly, her total wealth on month $t + 1$ is

$$W_{t+1} = [(1 - \omega_t) \exp(r_{t+1}^f) + \omega_t \exp(r_{t+1}^f + r_{t+1})]W_t, \quad (13)$$

where the equity risk premium, r_{t+1} , and the risk-free interest rate, r_{t+1}^f , are continuously compounded. We assume that the investor maximises the short-term expected 1-month-ahead wealth which excludes any intertemporal hedging component in the choice of the portfolio weights. Hence, the portfolio

⁹The results of the significance tests for R_{OOS}^2 with the EW-LIN($k = 1$) as benchmark should be interpreted with caution in the context of the EW-MS forecasts since the MS models are non-linear in the parameters.

weights on month t are the solution to the following optimising problem

$$\omega_t^* = \arg \max_{\omega_t} E_t[U(W_{t+1})], \quad (14)$$

where the utility function $U(W_{t+1})$ is defined according to the investor's preferences. We consider an investor with mean-variance preferences and corresponding utility $U(W_{t+1}) = E_t[W_{t+1}] - \frac{\gamma}{2} Var_t[W_{t+1}]$, where the parameter γ reflects the investor's absolute risk aversion. In this mean-variance preferences setting, the optimal proportion of wealth allocated to equities on month $t + 1$ is

$$\omega_t^* = \frac{\exp(\hat{r}_{t+1} + \hat{\sigma}_{t+1}^2/2) - 1}{\gamma \exp(r_{t+1}^f) \exp(\hat{\sigma}_{t+1}^2 - 1) \exp(2\hat{r}_{t+1} + \hat{\sigma}_{t+1}^2)}, \quad (15)$$

where \hat{r}_{t+1} is the OOS model-based forecast of the equity premium or predicted mean excess return, and $\hat{\sigma}_{t+1}^2$ is the OOS predicted variance; following Neely *et al.* (2014) and Campbell and Thompson (2008) *inter alia*, we obtain the latter as the sample variance estimated over the past five-year rolling window of historical monthly excess returns in order to allow for a time-varying variance.

We also consider an investor with constant relative risk aversion (CRRA) preferences, or power utility $U(W_{t+1}) = W_{t+1}^{1-\gamma}/(1-\gamma)$, where γ reflects the investor's coefficient of relative risk aversion, in order to parsimoniously capture the higher moments of the portfolio return distribution. In this CRRA preferences setting the optimal portfolio weight is given by

$$\omega_t^* = \frac{\hat{r}_{t+1} + \hat{\sigma}_{t+1}^2/2}{\gamma \hat{\sigma}_{t+1}^2}, \quad (16)$$

where \hat{r}_{t+1} and $\hat{\sigma}_{t+1}^2$ are the predicted mean and variance, as explained above.

We compare the asset allocation effectiveness of different forecasts using the Sharpe ratio and the certainty equivalent return (CER).¹⁰ The CER of a mean-variance utility investor is given by the average realised utility over the OOS period

$$CER = J^{-1} \sum_{j=0}^{J-1} U(W_{t+j+1}) = \hat{\mu}_p - \frac{\gamma \hat{\sigma}_p^2}{2}, \quad (17)$$

with $\hat{\mu}_p$ and $\hat{\sigma}_p^2$ the realised mean and variance of the portfolio excess returns over the OOS period,

¹⁰The CER is the risk-free rate of return that an investor considers equal (in terms of expected utility) to a different expected return which is higher but also riskier. The CER varies across investors because of their different risk tolerance. Thus if $CER_A > CER_B$ where A and B denote two competing forecasts used as alternative inputs to solve Equation (14) for asset allocation, the forecast A entails higher expected utility for the investor than the forecast B.

and γ the investor’s absolute risk aversion. The CER of a power utility investor is given by

$$\text{CER} = \left[\frac{(1 - \gamma)}{J} \sum_{j=0}^{J-1} \frac{W_{t+j+1}^{1-\gamma}}{1 - \gamma} \right]^{1/(1-\gamma)} - 1, \quad (18)$$

where γ is the investor’s relative risk aversion and W_{t+j+1} is as defined in Equation (13).

Our forecast evaluation metric is the CER gain, Δ , defined as the difference between the CER of a investor who employs a model-based forecasting approach and the CER of a investor that assumes no predictability and, accordingly, simply relies on the historical average. The test of $H_0 : \Delta \leq 0$ against the alternative $H_a : \Delta > 0$ is done using McCracken and Valente (2018) test with the critical values estimated by their proposed bootstrap method. We report the annualised Δ , obtained by multiplying the monthly CER gain by 1200. $\Delta > 0$ can be interpreted as the annualised fee that an investor would be willing to pay in order to have access to the model-based forecast.

5 Empirical results

The analysis is based on 1-step-ahead OOS forecasts constructed recursively using expanding windows. The first estimation window spans the 180-month period from December 1950 to December 1965; the second window spans 181 months and so forth. Thus, the first forecast $\hat{r}_{t+j+1}(j = 0)$ is for January 1966 and the last forecast, $\hat{r}_{t+j+1}(j = J - 1)$ is for December 2017; $J = 224$ forecasts. Appendix A gathers all the model and forecast-accuracy abbreviations employed in the paper.

5.1 Business-cycle dating with technical indicators

We begin by showing empirically that the agreement technical indicators constructed from equity market prices and/or volume data serve as real-time business cycle indicators. Table 1 reports the *hits* or frequency with which each agreement technical indicator, as defined in Section 2, anticipates an expansion for month $t + 1$ and the month is classified as such by the NBER-dating; likewise, for recession months. We also report the frequency of transitions (from expansion to recession or vice versa) according to each technical indicator to compare it with the actual NBER cycle transition which is 2.61% over the sample months. Overall, the recession (expansion) hits range between 60.8% and 86.3% (53.7% and 90.0%) across technical indicators, and the frequency of transitions between

5.7% and 12.5%. There is no agreement indicator which is the best one according to hits and state transition. Bearing this in mind, the agreement indicator is selected every time we do a forecasting. As an illustration we plot the $A_{10,t}$ indicator over the entire sample period together with shaded areas that indicate NBER-dated recessions, Figure 1 provides visual evidence that technical indicators signal rather well the month-ahead economic state.

[Insert Table 1 around here]

5.2 Results from statistical evaluation of combined forecasts

Tables 2 and 3 report the results when the forecast covers all the period (January 1966 to December 2017) and from January 1976, respectively. The two period are similar to the periods considered by Welch and Goyal (2008) and Rapach *et al.* (2010)¹¹. The second period is motivated by the results of Welch and Goyal (2008) which suggest that the OOS predictive ability of several macroeconomic variables for the equity premium deteriorates sharply after the dramatic oil price shocks that occurred during the 1973-1975 period. Panel A focuses on LIN models. Panels B and C report the results on TSR models with the agreement technical indicators $A_{p,t}$ as observable. Panel D and E report the performance of the MS models. We also report in Panel F linear models that employ as predictors the first three principal components (PC) of either the set of 12 macroeconomic variables, the 14 technical indicators or all 26 of them. Panel G and H report the results using gradient boosting and random forest, respectively.

[Insert Tables 2 and 3 around here]

Focusing on the statistical criteria, we now compare the EW combined combined equity premium forecasts from complete-subset $k = \{1, 2, 3\}$ models within the LIN, TSR and MS families, and also with the linear model with principal components as explanatory variables and the decision tree methods discussed in Section 3. R_{OOS}^2 , the reduction in mean squared error attained by the model-based forecast at hand versus the traditional HA benchmark, Equation (11), is used as statistical performance criterion. It is computed over all the OOS months and separately over NBER-dated business cycle expansion and recession months. The column labelled EW($k=1$) reports a variant of the R_{OOS}^2 statistic using instead as benchmark the EW-LIN($k = 1$) forecast combination of Rapach *et al.* (2010).

¹¹The difference is that they use quarterly data and the prediction starts in 1965.

Comparing the R_{OOS}^2 values for expansion and recession months suggests that the additional value of model-based approaches versus the HA benchmark is more noticeable in recessions than in expansions. During both periods the gradient boosting method had the worst performance with negative values of R_{OOS}^2 . In general the performance of MS model, linear model with PC as regressors and the random forest method are also not good, especially during the expansion periods.

Regarding to linear models, the results not only serve to confirm those in Rapach *et al.* (2010) from EW-LIN($k = 1$) combined forecasts, but also reveal that this is a pervasive finding from the perspective of more general forecasting approaches such as EW-LIN($k = \{2, 3\}$) models. Moreover, relative to the mostly negative R_{OOS} values obtained for the individual simple LIN models¹², the positive and relatively large R_{OOS}^2 attained in Table 2 (Panel A, EW-LIN) reaffirm the usefulness of the forecast combination approach. To illustrate, over all the OOS months, for the simple simple LIN model, the largest R_{OOS}^2 is equal to 0.260¹³, which is by and large improved by the $R_{OOS}^2 = 0.81$ of the EW-LIN($k = 1$) forecasts. The forecast performance measures shown in Panel A also reveal in the novel context of the equity premium that the combination of complete-subset 2-predictor EW-LIN($k = 2$) models or 3-predictor EW-LIN($k = 3$) models notably improves upon the combination of simple LIN models. In fact, the statistics shown in the fourth column labelled EW($k = 1$) suggest that the EW-LIN($k = 2$) and EW-LIN($k = 3$) predictions significantly reduce the MSE of the EW-LIN($k = 1$) prediction.

Moving beyond the LIN models, we also appraise the two-state EW-TSR and EW-MS models. The comparison of R_{OOS}^2 for a given k across families of models (Panels A to D) suggests that the regime-switching EW-TSR family based on an observable state variable attains superior forecast accuracy gains not only than the EW-LIN models but also than the EW-MS models based on a latent state variable which are less parsimonious (involving a transition probability matrix) and computationally more demanding. In general, comparing EW-TSR models with the same or different intercept, none of them clearly dominated the other. We also considered linear models that employ as predictors the first three principal components (PC) of either the set of 12 macroeconomic variables, the 14 technical indicators or all 26 of them. This type of forecasts, known as diffusion indices in the literature, have been shown not to outperform the combined forecasts; see Rapach and Zhou (2013) and Neely *et al.* (2014). The results presented in Panel F shows a good performance in the full sample period. However, the performance is relatively poor in the expansion period, as borne out by the R2OOS. Moreover, the

¹²Results not presented because is similar to the results presented in Rapach *et al.* (2010)

¹³Result for individual variables not presented here; see previous footnote.

performance generally improves when using only the technical indicators.

The main lesson from these results is that constructing equity premium predictions from EW threshold regression models that extend the conventional linear regressions by introducing a predictability state via a technical indicator is very effective.

Figure 2 plots the two components of the equity premium forecast MSE over the entire OOS period, namely, the squared forecast bias and the forecast variance (Theil (1971)).¹⁴ We plot the results for the simple LIN models, the EW combinations thereof, as well as the EW combinations of the two-state TSR and MS models. To keep the graph readable, we just display the results for the forecast combination of models with one macroeconomic predictor ($k = 1$). The results suggest that the combined forecasts (from either LIN or TSR models) have lower variance than the forecasts from all of the individual LIN models. Finally, the graph also reveals that the TSR models that allow for regimes of equity premium predictability have lower forecast variance than the LIN models.

[Insert Figure 2 around here]

To appraise the OOS forecast performance dynamically over time, we plot in Figure 3, left column, the CSE discussed in Section 3 for the HA benchmark minus the CSE for combined forecasts. We present the results for EW-LIN, EW-TSR and EW-MS models. The EW-TSR and EW-MS models are with the same intercept. We observe that the predictive ability of EW-LIN combined forecasts begins to deteriorate in the late 1990s while that of the EW-MS combined forecasts begins to deteriorate much earlier. On the other hand, the graphs corresponding to the EW-TR forecasts are predominantly upward sloped.¹⁵ Overall, the evidence from this dynamic forecast evaluation reinforces our early findings from the static evaluation. Specifically, they confirm that the forecast combination from TR models that parsimoniously allow for two predictive states (expansion versus recession) through a technical indicator consistently outperform the combination of forecasts from simple LIN models. Finally, Figure 3, right column, plots the CSE of the EW-LIN($k = 1$) combination of Rapach *et al.* (2010) minus the CSE of the EW-LIN($k = 2$) or EW-LIN($k = 3$) combinations in the first graph, the

¹⁴The forecast $MSE = E[(r_{t+j+1} - \hat{r}_{t+j+1})^2]$ can be estimated as $[\sum_{j=0}^{J-1} (\hat{r}_{t+j+1} - r_{t+j+1})/J]^2$ which can be decomposed as the squared forecast bias $[(\sum_{j=0}^{J-1} \hat{r}_{t+j+1} - r_{t+j+1})/J]^2$ and the forecast variance $\sum_{j=0}^{J-1} (\hat{r}_{t+j+1} - \bar{\hat{r}})^2/J$, where $\bar{\hat{r}}$ is the mean of $\hat{r}_{t+j+1}, j = 0, \dots, (J - 1)$.

¹⁵Unreported graphs for diffusion indices (i.e., linear forecasts based on the first three principal components of all macroeconomic variables and/or technical indicators) show a dropoff from the mid to late 1970s, a sharp increase between 1980 and 1985, a large dropoff thereafter until the late 1990s followed by another rise. This evidence suggests that diffusion indices behave more erratically than the EW-LIN forecasts, in line with the findings in Rapach and Zhou (2013).

EW-TR combinations in the third graph, respectively, and the EW-MS combinations in the fifth and sixth graphs, respectively. The results are qualitatively similar.

[Insert Figure 3 around here]

5.3 Results from economic evaluation of combined forecasts

It is well known that the forecast rankings stemming from utility-based criteria and statistical criteria do not necessarily come hand in hand (see e.g., Rapach and Zhou (2013) and Andrada-Felix *et al.* (2016) *inter alia*). Thus, for completeness we present in Tables 2 and 3, for the whole and crisis periods respectively, the results from the asset-allocation exercise outlined in Section 4.2 for a representative mean-variance utility investor with absolute risk aversion parameter $\delta = 5$, and a CRRA preferences investor with relative risk aversion parameter $\delta = 5$.

Concurrent with the evidence from the statistical forecast evaluation, the portfolio analysis suggests that the gradient boosting is not very effective whereas the forecast combination based on TSR models is the most fruitful. However, the performance of the combination of the MS models and linear models are now similar. To illustrate, for the full period, the TSR models for $k = 3$ provide sizeable CER gains of 3.32 and 3.20 in Panels B and C, respectively, versus 2.64 (LIN models in Panel A) and 2.62 and 2.33 for MS models in Panel D and E, respectively. A similar result occurs for a CRRA utility investor. Thus both the statistical and economic criteria, the results indicate that the agreement technical indicators $A_{p,t}$ are very effective state variables for equity premium prediction. Regarding the linear models, Panel A, an analysis reveals that the forecast combination of LIN($k = 1$) models is improved upon by the forecast combination of complete-subset LIN($k = 2$) and LIN($k = 3$) models. For instance, for the full period, with a $\Delta(\%)HA$ of 2.64 (mean-variance investor) and 2.62 (CRRA investor) the EW-LIN($k = 3$) combined forecasts deliver a superior CER gain versus the HA benchmark than the EW-LIN($k = 1$) combined forecasts with smaller $\Delta(\%)HA$ values of 1.57 and 1.78, respectively. The improvement using complete-subset $k = \{2, 3\}$ combinations compared to complete-subset $k = 1$ combinations, also happens with TSR and MS models (see panels B to E). For the crisis period the conclusions are similar.

5.4 Robustness checks

We carry out several robustness checks to assess if the above results are challenged, first when we consider only most recent period¹⁶. This third period, 2000-2017 gives relatively more weight to the late 2000s global financial crisis. The statistical and economic results in Table 4 confirms most of the previous results. In particular, EW-TSR models outperform the combination of LIN models for any $k = \{1, 2, 3\}$, except in term of R_{OOS}^2 for the case without intercept and $k = 3$. The PCA method has also a good performance when the components are evaluated considering either the technical indicators or jointly the macroeconomic and technical indicators. However, when considering only the macroeconomic variables the performance is worse than the linear models.

[Insert Tables 4 and 5 around here]

Second, in the spirit of Cenesizoglu and Timmermann (2012), we also evaluate the asset allocation exercise by considering a CRRA parameter equal to 3 and 10. The results, presented in Table 5, confirm the better performance of EW-TSR models.

6 Summary and concluding remarks

This paper expands the equity-premium predictability literature by proposing the combination of state-dependent models which interact macroeconomic predictors with a binary technical indicator as observable state variable to capture the state of the economy. The OOS forecast accuracy of the models is compared with that of existing equity premium forecasting strategies that combine with EW simple linear models or Markov-switching models. The evaluation of equity premium forecasts is based not only on statistical criteria but also on economic criteria such as the asset-allocation problem of an investor. The analysis is based on monthly data from December 1950 to December 2017 for the S&P500 equity index. The findings suggest that the proposed approach contributes to delivering stable OOS gains. The threshold regression models offer superior forecast accuracy to existing linear (one-state) specifications, and also to more heavily parameterised and computationally demanding Markov-switching models where the state variable is latent. Besides, we found an improvement using complete-subset $k = \{2, 3\}$ combinations compared to complete-subset $k = 1$ combinations with LIN, TSR and MS models (see panels B to E). For the crisis period the conclusions are similar. Finally, the

¹⁶Similar to Rapach *et al.* (2010) the forecast period starts on January 2000.

machine learning methods, random forest and gradient boosting presented a worst performance than the combined traditional regression models. These findings are not challenged by different forecasting sub-periods, alternative investor's risk aversion levels, and rolling (versus expanding) estimation windows.

A List of abbreviations

Models

A_{τ}^{TECH}	Agreement technical indicators, function of the 14 technical indicators
EW	Equally-weighted combination of all forecasts from complete-subset models
EW-LIN	Equally-weighted combination of forecasts from linear models
EW-MS	Equally-weighted combination of forecasts from MS models
EW-TR	Equally-weighted combination of forecasts from TR models
LIN	Linear regression model
MA(a, b)	Moving-average technical indicator with a and b months
MOM(l)	Momentum technical indicator with l months
MS	Two-state Markov-switching regression model with latent state variable
TSR	Two-state threshold regression model with A_{τ}^{TECH} as observable state variable
VOL(a, b)	Volume- and price-based technical indicator with a and b months

Forecast evaluation

CER	Certainty equivalent return or risk-free return that an investor considers equal (in terms of expected utility) to a higher but risky expected return
CRRA	Constant relative risk aversion or power utility investor
CSE	Cumulative square error of HA minus cumulative square error of forecast at hand
HA	Historical average (as benchmark forecast)
MSE	Mean squared (prediction) error
MV	Mean-variance utility investor
OOS	Out-of-sample
$\Delta(\%)HA$	CER of forecast at hand minus CER of historical average benchmark
$\Delta(\%)EW$	CER of forecast at hand minus CER of EW-LIN($k = 1$) forecast benchmark

Table 1: **Business-cycle dating with technical indicators.** The table reports the hits or frequency with which agreement technical indicator computed with information up to month t signals a state (expansion or recession) for month $t + 1$ which coincides with the NBER-dating. The sample period is January 1951 to December 2017. It also reports the percentage of transitions from one state to another over the sample months.

	Agreement $A_{\tau,t}$ indicators			
	Hits(%)			Transitions (%)
	All	Exp	Rec	
A_1	55.5	90.9	60.8	12.5
A_2	63.4	87.6	67.0	11.7
A_3	68.2	86.0	70.9	11.0
A_4	71.2	85.1	73.3	10.7
A_5	73.9	83.5	75.4	9.7
A_6	76.4	80.2	77.0	10.0
A_7	80.5	76.9	80.0	8.5

A_{14}	92.1	53.7	86.3	7.0

Table 2: **Statistical and economic evaluation of equity premium forecasts.** The table reports statistical (left panel) and economic (right panel) measures to assess the accuracy of out-of-sample EW combined forecasts over the OOS period from January 1966 to December 2017. The underlying forecasts are from the LIN models (Panel A), two-state threshold regression (TSR) model with same intercept and different intercepts (Panels B and C, respectively), and Markov Switch (MS) model with same intercept and different intercepts (Panel D and E, respectively), principal component analysis (PCA, Panel F), Gradient Boosting (Panel G) and Random Forest (Panel H). The R_{OOS}^2 measures the reduction in MSE attained by the model-based forecast at hand relative to the HA benchmark (2-4 columns) or relative to the EW-LIN($k = 1$) combination of Rapach *et al.* (2010) as benchmark (column labelled EW($k=1$)). The hypothesis $H_0: R_{OOS}^2 \leq 0$ against $R_{OOS}^2 > 0$ is tested using the Clark and West (2007) MSE-adjusted statistic. The table also summarises the asset-allocation value of each predictor for a mean-variance (MV) utility investor with absolute risk aversion parameter of 5, and a CRRA preferences investor with relative risk aversion parameter of 5. $\Delta(\%)$ is the annualised certainty equivalent return (CER) gain versus the HA benchmark. The hypothesis $H_0: \Delta(\%) \leq 0$ against $\Delta(\%) > 0$ is tested using the McCracken and Valente (2018) test. In all tests: *, ** and *** indicate rejection at the 10%, 5%, and 1% significance levels. Bold denotes the best two models and italics denotes the worst two models according to each criterion.

Figure 1: Plot of the recession months as signalled by the agreement (of technical indicators) variable A_{10} . Shaded areas indicate recession months according to NBER business cycle dating. The sample period is from December 1950 to December 2017.

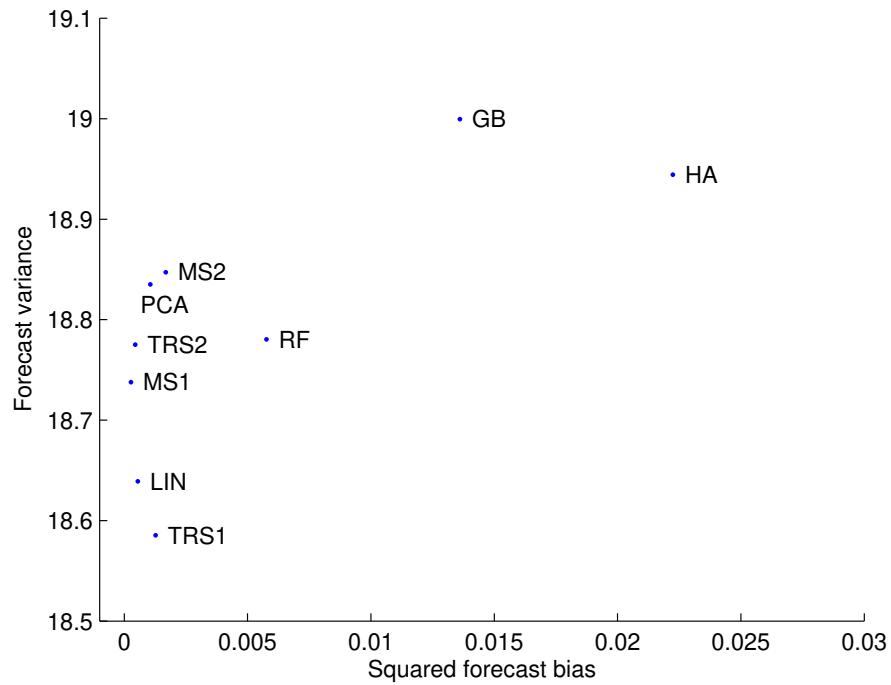

Figure 2: The figure provides a scatterplot of the out-of-sample forecast variance against the squared forecast bias for the combination of linear models (LIN), two-state threshold regressions with same (TRS1) and different (TRS2) intercepts, two-state Markov-Switching with same (MS1) and different (MS1) intercepts, principal-component analysis (PCA), random-forest (RF) and gradient boosting (GB). For each type of model, the forecasts being combined are those arising from the complete-subset specifications with one predictor ($k = 1$). The OOS period is from January 1966 to December 2017.

Table 5: **Asset allocation exercise for $\gamma = 3$ and $\gamma = 10$** : The table reports economic (right panel) measures to assess the accuracy of out-of-sample EW combined forecasts over the OOS period from January 1966 to December 2017. The underlying forecasts are from the LIN models (Panel A), two-state threshold regression (TSR) model with same intercept and different intercepts (Panels B and C, respectively), and Markov Switch (MS) model with same intercept and different intercepts (Panel D and E, respectively), principal component analysis (PCA, Panel F), Gradient Boosting (Panel G) and Random Forest (Panel H). The investor who allocates his wealth between stocks and risk-free bills at the end of each month is assumed to have a mean-variance or constant relative risk aversion (CRRA) preferences and a relative risk aversion parameters $\gamma = 3$ (left panel) and $\gamma = 10$ (right panel). $\Delta(\%)$ is the annualised certainty equivalent return (CER) gain versus the HA benchmark. The hypothesis $H_0: \Delta(\%) \leq 0$ against $\Delta(\%) > 0$ is tested using the McCracken and Valente (2018) test: *, ** and *** indicate rejection at the 10%, 5%, and 1% significance levels. Bold denotes the best two models and italics denotes the worst two models according to each criterion.

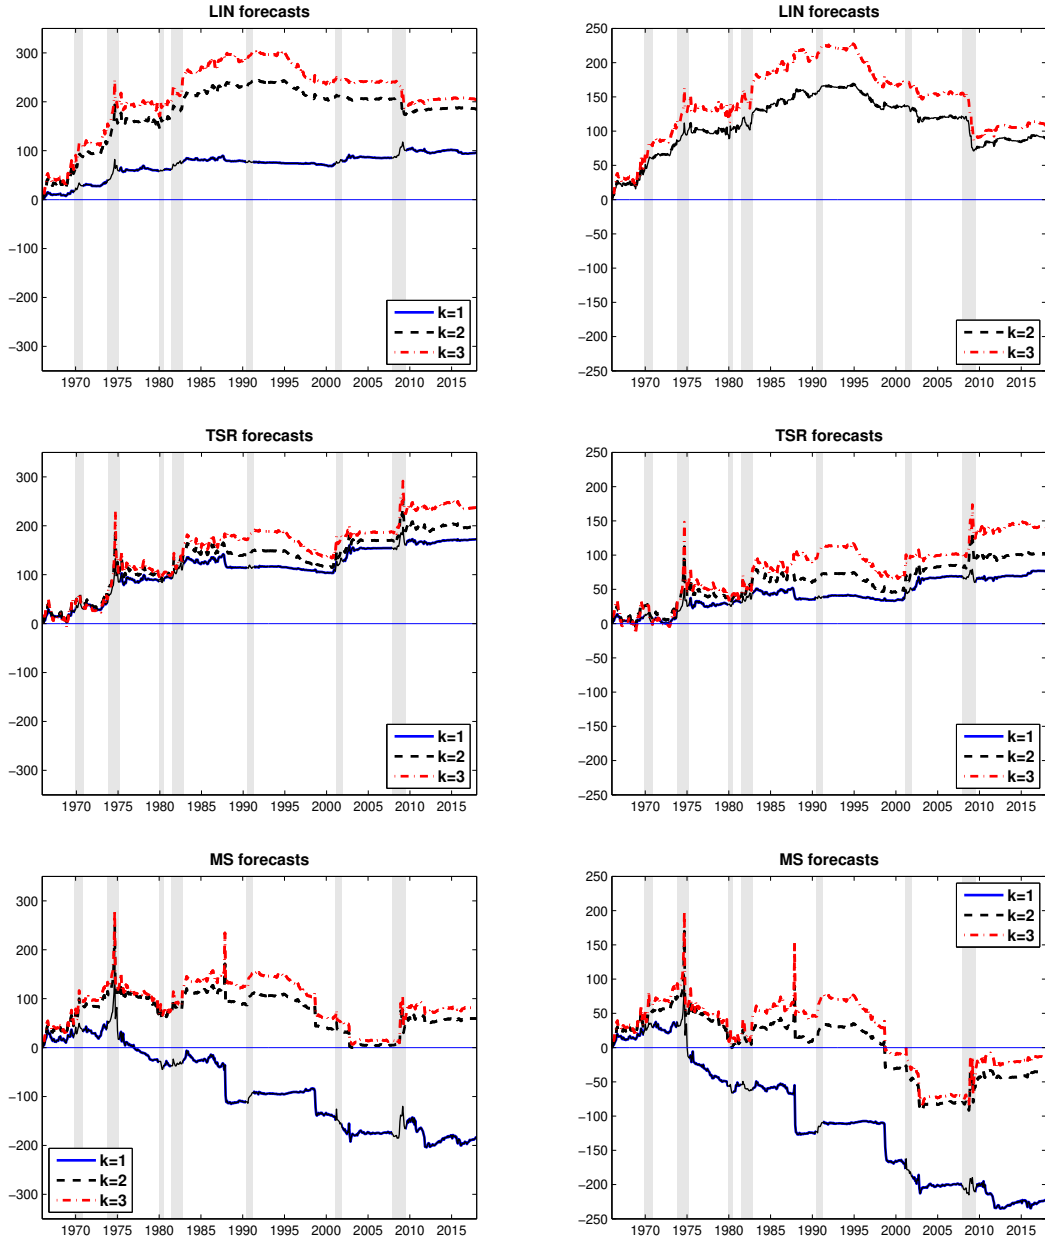

Figure 3: Plots of ΔCSE_t defined as the cumulative squared forecast errors of the historical average (HA) benchmark model minus the cumulative squared forecast errors from combination of forecasting methods (on the left) and the cumulative squared forecast errors of the combining EW-LIN ($k = 1$) combination of Rapach *et al.* (2010) benchmark model minus the cumulative squared forecast errors from combination of forecasting methods (on the right) over the out-of-sample period from January 1966 to December 2017. We consider EW-LIN model and EW-TSR and EW-MS models, both with the same intercept, as predictive models. The candidate predictors are the set of 12 macroeconomic variables considered either in single-, two- or three-variable regressions ($k = 1, 2, 3$).
